Pan Ming Huang (1934-2009)

Editor in Chief

Dr. Pan Ming Huang died on September 13, 2009, after a short illness. He was a towering leader in the field of soil science, and soil chemistry in particular, having served the profession for over 44 years formerly as professor of soil science at the University of Saskatchewan, Saskatoon, Saskatchewan, Canada. He was a dedicated teacher and author of over 300 journal articles published in the most prestigious journals. In the midst of the revision of the *Handbook of Soil Sciences*, having developed and approved the outline, set the standards for the contributions, and solicited the cooperation of all the associate editors, he unexpectedly fell ill. One of his strengths was his ability to involve, organize, and inspire colleagues to cooperate in pursuing scientific endeavors as was evidenced by his initial inputs into this work. Unfortunately, he passed away before being able to see any of the fruits of his labors, the completed manuscripts. Dr. Huang is survived by his wife, Yun Yin, who was gracious in the handover of all the materials required for us to complete the handbook in a timely manner. We dedicate this book to Dr. Huang as a lasting memorial to his many contributions to soil science.

Preface

Handbook of Soil Sciences is the second edition of a comprehensive reference work on the discipline of soil science as practiced today. The new edition has been completely revised and rewritten to reflect the current state of knowledge. It contains definitive descriptions of each major area in the discipline, including its fundamental principles, appropriate methods to measure each property, many examples of the variations in properties in different soils throughout the world, and guidelines for the interpretation of the data for various applications (agricultural, engineering, and environmental).

This handbook assembles the core of knowledge from all fields encompassed within the discipline of soil science. It is a resource rich in data, which will provide professional soil scientists, agronomists, engineers, ecologists, biologists, naturalists, and students with their point of first entry into a particular aspect of soil science. The contributions serve those professionals seeking factual reference information on a particular aspect. The handbook provides a thorough understanding of soil science principles and practices based on a rigorous, complete, and up-to-date treatment of the subject matter compiled by the leaders in each field. In general, the following critical elements are present in each part: description of concepts and theories, definitions, approaches, methodologies and procedures, data in tabular and figure forms, and extensive references.

The handbook is organized into two books comprising nine parts, covering the six traditional areas of soil science together with a new part dealing with interfacial interactions among the physical, chemical, and biological regimes within the soil, a part on the interdisciplinary aspects, and a final part on databases. The two books are organized as follows:

Handbook of Soil Sciences: Properties and Processes

Part I: Soil Physics Part II: Soil Chemistry Part III: Soil Mineralogy

Part IV: Soil Biology and Biochemistry

Part V: Pedology

Handbook of Soil Sciences: Resource Management and Environmental Interactions

Part I: Soil Physical, Chemical, and Biological Interfacial Interactions

Part II: Soil Fertility and Plant Nutrition

Part III: Interdisciplinary Aspects of Soil Science

Part IV: Soil Databases

The subdivision of each part into a series of chapters was made by the associate editors and, in some cases, may appear to be somewhat arbitrary. The chapters have been arranged in such a way as to produce a thread running through each part. A complete table of contents, which is provided at the beginning of each book, gives a general outline of the scope of the covered subject material. In addition, a comprehensive subject index and an assemblage of units in common usage in soil science are provided at the end.

When the revision of this work was started, Dr. Pan Ming Huang, who was the associate editor for the soil chemistry part in the first edition, took on the role of editor in chief. Tragically and unexpectedly, he passed away in September 2009 in the midst of overseeing this expansive work. At short notice, the publisher approached us to complete this massive task to which we agreed in November 2009. Posthumously, we wish to recognize the vision, hard work, and dedication of our friend and colleague, Dr. Huang, in developing the revised outline of the book and soliciting the participation of all the associate editors and, in turn, the authors.

The chapters of this handbook have been written by many authors, all experts in their own fields, and peer-reviewed by independent reviewers. The nine parts have been carefully edited and integrated by the associate editors, all distinguished soil scientists in their own fields. This handbook is a tribute to the dedication of the authors, associate editors, and the publisher and its editorial associates. We wish to thank all the authors for their valuable contributions, the many nameless reviewers for their useful and helpful comments and criticisms, and the associate editors for all their hard work that they willingly contributed.

xii Preface

We also wish to recognize John Sulzycki who was highly effective in twisting our arms to pick up the threads and continue with the project after Dr. Huang's death, Randy Brehm who continued with the management of this project, and Jill Jurgensen, Vinithan Sethumadhavan, and Suganthi Thirunavukarasu who dealt with the minutiae of the editorial process. In addition, several research associates, graduate and undergraduate

students, and visiting scientists, especially Helena Ren, Gaelan Jones, and David Li at the Tropical Research and Education Center, University of Florida, helped us in the editorial process for which we are duly grateful. Finally, we would like to thank our wives, Priscilla and Zhitong, for their patience, sacrifice, understanding, support, and encouragement without which this project would not have been possible.

Editors

Dr. Pan Ming Huang (deceased) was the professor emeritus of soil science at the University of Saskatchewan, Saskatoon, Saskatchewan, Canada, and served for 44 years in that institution. He received his BSc (1957) from the National Chung Hsing University, Taiwan; his MSc (1962) from the University of Manitoba; and his PhD (1966) from the University of Wisconsin, Madison, Wisconsin. His research work significantly advanced the frontiers of knowledge on the formation, chemistry, nature, and surface reactivity of mineral colloids, organic matter, and organomineral complexes in soils and sediments and their role in the dynamics, transformations, and fate of nutrients, toxic metals, and xenobiotics in terrestrial and aquatic environments. His research findings, embodied in well over 300 refereed scientific publications, are fundamental to the development of sound strategies for managing land and water resources in the Earth's critical zone. In addition to developing and teaching courses in soil physical chemistry and mineralogy, soil analytical chemistry, and ecological toxicology, he trained and inspired MSc and PhD students and postdoctoral fellows, and received visiting scientists from all over the world. He served on numerous national and international scientific and academic committees. He also served as a member of editorial boards, including the Soil Science Society of America Journal. He served the International Union of Pure and Applied Chemistry and the International Union of Soil Sciences in a number of capacities. He received the Distinguished Researcher Award from the University of Saskatchewan, the Soil Science Research Award from the Soil Science Society of America, the Distinguished Alumnus Award and the Chair Professorship Award from the National Chung Hsing University, and the Y. Q. Tang Chair Professorship Award from Zhejiang University. He was a fellow of the Canadian Society of Soil Science, the Soil Science Society of America, the American Society of Agronomy, the American Association for the Advancement of Science, and the World Innovation Foundation.

Dr. Yuncong Li is the University of Florida Research Foundation (UFRF) professor of soil science in the Department of Soil and Water Science at the Tropical Research and Education Center, Institute of Food and Agricultural Sciences (IFAS), University of Florida in Homestead, Florida. He received his BS (1982) in soil science and agricultural chemistry from the Shandong

Agricultural University, China; his MS (1990) in agronomy from the University of Georgia; and his PhD (1993) in environmental science from the University of Maryland. He is also an affiliated professor at the University of Florida's Center for Tropical Agriculture, Hydrologic Sciences Academic Cluster, School of Natural Resources and Environment, and Water Institute, and a courtesy professor at the Shandong Agricultural University. He has received many awards and distinctions including a fellow of both the American Society of Agronomy and the Soil Science Society of America, Food and Agriculture Organization (FAO) Fellow, Wilson Popenoe Award (InterAmerican Society for Tropical Horticulture), Outstanding Paper Award (Florida State Horticultural Society), Jim App Award (University of Florida), Junior Faculty Research Award (Sigma Xi, the international honor society of science and engineering), Senior Faculty Award (Gamma Sigma Delta, the honor society of agriculture), Research Innovation Award (University of Florida), Wachovia Extension Professional Award (Extension Association of Florida), and Research Foundation Professor Award (University of Florida). His research and extension program focuses on water and soil quality monitoring, assessment and remediation, management practices to improve nutrient use efficiency, and nutrient cycling in soils/sediments. He has authored or coauthored over 160 research papers, 70 extension articles, and 15 book chapters. He recently edited a book, Water Quality Concepts, Sampling, and Analyses (Taylor & Francis). He serves as an associate editor for Critical Reviews in Environmental Science and Technology and Communications in Soil Science and Plant Analysis. Additionally, he has chaired or cochaired 20 graduate students, served as a committee member for 24 other graduate students, and supervised 15 postdoctoral fellows and many international visiting scientists.

Dr. Malcolm E. Sumner is the Regents' professor emeritus of environmental soil science in the Department of Crop and Soil Sciences at the University of Georgia, Athens, Georgia. He received his BSc Agriculture (1954) in chemistry and soil science and his MSc Agriculture (cum laude) (1957) in soil physics from the University of Natal, South Africa, and his DPhil (1961) in soil chemistry from the University of Oxford, Oxford, United Kingdom. His alma mater, the University of Natal, awarded him an honorary doctor of science degree in recognition of his career

xiv Editors

contributions to soil science. Before coming to the University of Georgia, he was professor and head of the Department of Soil Science and Agrometeorology at the University of Natal, South Africa. He has spent sabbatical leaves at the Agricultural University (Wageningen, the Netherlands), University of Missouri (Columbia), University of Wisconsin (Madison), University of Newcastle-upon-Tyne (United Kingdom), Vista University (South Africa), University of Adelaide (Australia), and the Commonwealth Scientific and Industrial Research Organization (CSIRO) (Australia). Over 90 graduate students and postdoctoral associates have studied under his guidance in South Africa and the United States where he taught courses in soil chemistry, soil physics, and soil fertility. In addition to being a fellow of both the American Society of Agronomy and the Soil Science Society of America, he holds the Agronomic Research Award and the Werner L. Nelson Award for Diagnosis of Yield Limiting Factors from the American Society of Agronomy and the Soil Science Research Award, International Soil Science Award, and the Soil Science Distinguished Service Award from the Soil Science Society of America. He is the holder of many other awards and distinctions including the Sir Frederick McMasters Visiting Fellowship (Australia) and the D. W. Brooks Faculty Awards for Excellence in Research and International Agriculture (University of Georgia). He has presented addresses at more than 100 universities and research institutions throughout the world on his research findings. He has also served as associate editor for the Soil Science Society of America Journal and is a member of editorial boards of many other journals. His published works cover a wide range of topics, including subsoil acidity, the agricultural uses of gypsum, diagnosis of yield-limiting factors, beneficial use of anthropogenic wastes, and transport of nutrients in soils. A widely respected author, Dr. Sumner's works include Soil Acidity (Springer-Verlag, 1991), Soil Crusting: Chemical and Physical Processes (Lewis Publishers, 1992), Suelos de la Agroindustria Cafetalera de Guatemala (University of Georgia, 1994), Distribution, Properties and Management of Australian Sodic Soils (CSIRO Publications, 1995), Sodic Soils: Distribution, Properties, Management, and Environmental Consequences (Oxford University Press, 1998), and the Handbook of Soil Science (CRC Press, 1999). He has authored or coauthored over 350 scientific papers, including 220 refereed journal articles, and has contributed chapters to over 30 books.

Associate Editors

Dr. Marion F. Baumgardner (Soil Databases) is a fellow of both the American Society of Agronomy and the Soil Science Society of America. He is professor emeritus of agronomy at Purdue University. He has received the International Soil Science Award and the Distinguished Service Award from the Soil Science Society of America. During his 39 years on the faculty at Purdue University, he focused his research interests on the quantitative relationships among the multispectral, physical, and chemical properties of soils and the application of aerospace remote sensing and spatial databases to the inventory and monitoring of soil resources at all scales from local to global. From the mid-1980s until his retirement in December 1997, he was active in research and development of the World Soils and Terrain Digital Database, known as SOTER. During the latter half of his career, his teaching included courses in soil and water conservation; soil, water, and air contamination; and remote sensing of terrestrial ecosystems. In retirement, he continues to be engaged in technical reviews and historical research and writing.

Dr. James J. Camberato (Soil Fertility) received his BS from the University of Massachusetts and his MS and PhD in soil science from North Carolina State University. He is currently associate professor of agronomy at Purdue University. He has conducted research and education programs in soil fertility and plant nutrition for 25 years in the Midwest and Southeast United States for agronomic crops and turfgrasses.

Dr. Pan Ming Huang (see Editors page)

Dr. Guy J. Levy (Interdisciplinary Aspects of Soil Science) is a senior soil scientist; since 1989 with the Institute of Soil, Water and Environmental Sciences, Agricultural Research Organization, Ministry of Agriculture and Rural Development, Israel. He obtained his BSc Agriculture (1981) and MSc Agriculture (1984) from the Hebrew University of Jerusalem, Jerusalem, Israel, and his DSc Agriculture (1988) from the

University of Pretoria, Pretoria, South Africa. His main research interests include characterization of soil-structural stability and its improvement with the aid of soil amendments, and sustainable use of treated wastewater and the application of waste material in agriculture. He has authored or coauthored over 100 peer-reviewed scientific papers and book chapters.

Dr. Antonio Violante (Soil Physical, Chemical, and Biological Interfacial Interactions) is professor of soil chemistry at the University of Naples Federico II, Italy, where he received his academic degrees in chemistry. Additionally, he has completed postdoctoral training at the University of Wisconsin, Madison, Wisconsin, and the University of Saskatchewan, Saskatoon, Saskatchewan, Canada. He was head of the Dipartimento di Scienze Chimico-Agrarie and coordinator of the Doctoral School in Agrobiology and Agrochemistry. He taught courses in agricultural chemistry, soil chemistry, environmental biogeochemisty, and soil mineralogy, and has conducted research on the interface between soil chemistry, mineralogy, and soil biology. Dr. Violante's areas of research include the formation mechanisms of Al-hydroxides and oxyhydroxides, the surface chemistry and reactivities of short-range ordered precipitation products of Al and Fe, the influence of biomolecules on the sorption/desorption of nutrients and xenobiotics on/from variable charge minerals and soils, the factors that influence the sorption and residual activity of enzymes on variable charge minerals and organo-mineral complexes, and the chemistry of arsenic in soil environments. He has been the chairman and chief organizer of international and national congresses, and has authored 180 refereed research articles, book chapters, and invited reviews and coedited 7 books. He is a fellow of both the Soil Science Society of America and the American Society of Agronomy. He is also chair of the Commission 2.5 of International Union of Soil Societies (IUSS).

What Is Soil?

Soil, the extremely thin but precious skin covering our planet, supports all terrestrial life forms and contributes nutrients to aquatic and marine environments. This covering of the unweathered and partially weathered geological formations at the Earth's surface is a unique, fragile veneer. No longer rock nor geological sediment, soil has been altered during the process of soil formation by geological, topographical, climatic, physical, chemical, and biological factors to form a living entity, which inextricably links inorganic or mineral particles with organic matter and biota bathed in a milieu of liquid water and gases. Water, the major constituent of all living entities, is the solvent and conveyor of nutrients, which, together with the solid phase, become the fertile substrate from which all planetary life springs. This nurturing and life-supporting pedosphere zone is a biologically active, porous, and structured medium that effectively integrates and dissipates mass fluxes and energy. In its pristine state, soil is a self-regulating, slowly evolving biogeochemical system that weathers with time, simulating sponge-like behavior and regulating and buffering nutrient supply and water quality and quantity for the growth of macro- and microflora and fauna. Furthermore, it determines the partitioning of water into surface and subterranean groundwater reservoirs.

In addition to its primary role in promoting, supporting, and sustaining all forms of life, soil also acts as a living filter for anthropogenic waste. Soil can recycle water through biochemically mediated processes that cleanse, purify, detoxify, and counteract most toxins and pathogens in polluted waters that would irreparably contaminate and degrade our environment. Despite being the repository of human and animal cadavers, including those from epidemics of pestilence and plague, all but a few vectors have been rendered harmless, and it is seldom, if ever, involved in the transmission of diseases. On the contrary,

soil has been the source from which great antidotes to disease and infection, the antibiotics, have been developed.

In ancient times, soil and water degradation, resulting in unsustainable crop production often due to the accumulation of salts, led to the downfall of civilizations. Directly or indirectly, the soil resource impacts, undergirds, and transcends all of society's urban, industrial, and agrarian interests. Current local to global policies and issues on conservation and sustainability, land use, energy, environmental quality, taxation, and food, feed, and fiber production are derived largely from the quality and extent of the available soil resource.

Despite the clearly pivotal role that soil plays in supporting life on Earth, a precise definition of soil is elusive. At this stage, one can say that soil is an evolving, living organic/inorganic covering of the Earth's surface, which is in dynamic equilibrium with the atmosphere above, the biosphere within, and the geology below. Soil acts as an anchor for roots, a purveyor of water and nutrients, a residence for a vast and still largely unidentified community of microorganisms and animals, a sanitizer of the environment, and a source of raw materials for construction and manufacturing. Soil is an essential component of terrestrial ecosystems used by nations as long-term capital to grow and develop. Because this foundation is essential to the life forms within and on it, one requires a fundamental understanding of this elastic, porous, three-phase system (solid, liquid, gas), and its components, processes, and reactions in order to be able to effectively manage and exploit this vital resource. In the words of Roy Simonson "Soil resources are the earthen looms that shape the lives of the people. The more completely they are understood, the better can be the fabric of life woven on these earthen looms" (Wilding et al., 1984).

Every soil consists of one to several layers, called horizons, a few to hundreds of centimeters thick that reflect the physical, chemical, and biological processes that have taken place during its formation. Horizons are composed of natural aggregates called peds, which are made up of associations of mineral and organic particles. Peds and particles are often separated from each other by pores that vary widely in size and shape. In addition, individual peds and particles may be coated by materials such as clay, organic matter, sesquioxides, or precipitated salts. Although the internal structure of peds is not readily visible to the naked eye, their spatial arrangement involving particles and pores (soil architecture) greatly influences soil behavior because

xxii Introduction

the organization is frequently systematic and related to macropore distribution. At the microscale, soil architecture governs soil water/solute movement and retention, soil structure/porosity, soil strength/failure, mineral synthesis/weathering, movement of toxic and nontoxic wastes, soil/root environments, root growth/proliferation, nutrient transfers, soil erosion, and oxidation/reduction reactions.

What Are the Soil Sciences?

Soil sciences are a spectrum of Earth sciences that address the importance of soils as very slowly renewable natural resources. They involve the study of soil formation, classification, and mapping; the physical, chemical, biological, and mineralogical properties of soil from microscopic to macroscopic scales of resolution; as well as the processes and behavior of soil systems and their use and management. Soils are integrative links between the atmosphere, biosphere, lithosphere, and hydrosphere. Soil sciences provide tools to integrate the components of Earth science systems, expanding knowledge of the causes and effects of spatial variability, and to take a more holistic approach to the dynamic processes affecting ecosystems.

Soil sciences focus primarily on near-surface processes that govern the quality and distribution of soil resources relative to landform evolution (geomorphology), geochemical environment (geochemistry), and organismal habitat (ecology/biology). Pedogenic processes are interactively conditioned by lithology, climate, and relief through geologic time. Soils are welded together into landscapes like chains; processes that perturb and impact higher topographic surfaces directly affect processes on adjacent surfaces below. Pedologists and other soil scientists study the energy flows and mass fluxes, which are the dynamic driving forces of pedogenesis through and over the three-dimensional soil system. They also quantify renewal and transfer vectors for biomass production, rainfall, and dusts, which counter constituent losses through drainage water, lateral interflow, and downslope migration or erosion products.

Soil sciences have their parentage in geology, chemistry, physics, and biology, but for the past 100 years have evolved as an independent, interdisciplinary body of knowledge with strong underpinnings to agriculture and, more recently, the environment. Because of an unparalleled success that soil sciences have enjoyed in helping to bring ample food, fiber, feed, and fuel to the world, the development of the basic soil sciences has evolved primarily as a by-product of research in agriculture, engineering, and the environment. There is growing evidence that the complexity of these problems requires a much broader approach to the science of the soil than can be stimulated by applied research alone. Soil sciences are taking their place alongside basic research efforts in the biosciences, geosciences, and atmospheric sciences to provide the reservoir of fundamental knowledge needed to develop lasting solutions to the challenges of balanced use and stewardship of the Earth. Despite the knowledge accumulated over the past century, Leonardo da Vinci's statement that "We know more about the movement of the celestial bodies than about the soil underfoot" is as true today as it was then. There is need for much more investigation of our most precious resource to stave off the fate that befell our ancestors in the ancient empires of Babylon, Egypt, China, Europe, and the Americas where soil degradation through nutrient loss, erosion, sodification, and salinization together with siltation of rivers and storage facilities laid waste their land and water resources. The ancients were constrained by their limited knowledge of processes driving the system, but we will be judged by generations to come based on our superior understanding of the soil system and the quality and stewardship of our land resources.

Modern parallels of soil and land degradation continue in both developing and industrialized countries. In addition to the problems facing the ancients that are still prevalent, chemical toxicities, irreversible land use conversion, environmental pollution, and desertification are the modern plagues. Sustainability of today's culture is threatened by loss of biodiversity, population growth, and land degradation, leading to enhanced greenhouse gas emissions culminating in global climate change. Land degradation is a complex technical, socioeconomic, and political issue without simple answers. Although soil scientists can provide technical solutions, without implementation as public policy, they are likely to be futile. Currently, public attention is focusing on soil, air, and water quality in efforts to maintain a clean environment. Soil sciences have a major role to play in this

What Is the Purpose of This Handbook?

Handbook of Soil Sciences is a revision of the first comprehensive reference on the disciplines of soil science as practiced today. It contains definitive descriptions of each major area in the disciplines, including fundamental principles, appropriate methods to measure each property, many examples of the variations in properties in different soils throughout the world, and guidelines for the interpretation of the data for various applications (agricultural, engineering, environmental, biological, regulatory, educational, hydrological, biogeochemical). This handbook assembles the current core of knowledge from all fields encompassed within the soil sciences and provides a resource-rich database that will give professional soil scientists, agronomists, engineers, ecologists, biologists, naturalists, and students their point of first entry into a particular aspect of the soil sciences. The contributions also serve those professionals seeking specific, factual reference information. The handbook provides a thorough understanding of soil science principles and practices based on a rigorous, complete, and cutting-edge treatment of the subject compiled by leading scientists in each field. It is designed as a desk reference book.

This handbook has been extended to two books, Handbook of Soil Sciences: Properties and Processes comprises five parts dealing with soil physics, soil chemistry, soil mineralogy, soil biology and biochemistry, and pedology. Handbook of Soil Sciences: Resource Management and Environmental Impacts discusses soil physical, chemical, and biological interfacial

Introduction xxiii

interactions; soil fertility and plant nutrition; interdisciplinary aspects of soil science; and soil databases.

In the *Handbook of Soil Sciences: Properties and Processes*, the part on soil physics opens with a description of the basic physical properties of soils followed by a treatment of their dynamic properties in relation to tillage and disturbance by machinery. Soil water is discussed, including content/potential relationships, its movement and transfer to the atmosphere both directly and through the plant, and the co-transport of solutes in moving water. The nature of soil structure and its bearing on soil behavior are explored followed by an examination of gas movement under unsaturated conditions. The role of macropores as the superhighway for bypass transport of water and solutes is considered. Thermal regime and heat transfer are discussed. Finally, the heterogeneity of soils is described culminating in an evaluation of spatial variability.

The part on soil chemistry begins with a discussion of the nature and dynamics of soil organic matter. The importance of the soil solution, for transport of nutrients and catalyst for reactions in soil, is then highlighted followed by an evaluation and description of the kinetics of reactions in soils. The reactions taking place when oxygen becomes limiting are then explored followed by a detailed account of soil colloidal phenomena important in predicting the behavior of the finest soil fraction. Ion exchange, sorption, and precipitation reactions are quantitatively treated as a framework to evaluate the behavior of labile constituents in soils. Catalytic reactions promoted by soil and its constituents are examined followed by an account of the effects of acidity and alkalinity on soil reactions and behavior.

Mineralogy of soils is covered in the next part starting with a discussion of the formation and occurrence of minerals in soils followed by three parts in which structure, occurrence, identification, and properties of phyllosilicates, oxide minerals, and poorly crystalline aluminosilicates are discussed. The part on soil biology and biochemistry begins with a discussion of viruses, bacteria, fungi, cyanobacteria and algae, followed by the topic of soil fauna comprising protozoa, nematodes, micro- and macro-arthropods, enchytriads, and vertebrates. The nature, function, and life cycles of each are described. Then the processes mediated by these organisms, including nutrient transformations, are discussed. A major portion of the discussion is devoted to nitrogen transformations because of their importance in soils.

Following a discussion of the geomorphology of soil landscapes and the pedogenic processes and models involved in soil formation, descriptions of the systems used to classify soils are presented in the part on pedology as a framework in which to discuss the soil orders in soil taxonomy and other classification systems. The part continues with a discussion of land evaluation followed by new chapters on hydropedology and subaqueous soils. Thereafter, digital soil mapping and its applications are presented, followed by a discussion of soil change in the anthropocene in which the bridge between pedology, land use, and soil management is built.

In the Handbook of Soil Sciences: Resource Management and Environmental Impacts, the new part on soil physical, chemical, and biological interfacial interactions opens with a discussion of the methodology to study metal(oid)s and nutrients at critical zone interfaces followed by insights into the interactions between clay and organic materials in soils. Various aspects of the involvement of nanoparticles in chemical, biological, and hydrological processes are discussed, followed by the effects of mineral and organic colloids on enzymatic activity in soils and its impact on biogeochemical processes. Thereafter, the effects of biophysical, biogeochemical, and biological processes on rhizosphere processes and reactions are discussed. Subsequent chapters deal with mineralogical, chemical, physical, and (micro) biological interactions involved in the turnover and stabilization of organic matter and the transformations of metal(oid)s. The part concludes with a discussion of the physicochemical and biological interfacial processes governing the fate and transport of nutrients and pollutants in soils.

Bioavailability of macro- and micro-nutrients as well as their interactions are discussed in the part on soil fertility and plant nutrition prior to evaluating methods for estimating their potential availability to crops and methods of application as fertilizers. The causes of soil acidity and strategies for its amelioration are also outlined. Finally, the efficiencies of nutrient and water use are discussed. Thereafter, various interdisciplinary aspects of soil science such as salinity, sodicity, water repellency, wetland biogeochemistry, acid sulfate soils, soils and environmental quality, soil erosion by wind and water, land application of wastes, and soil quality and conservation tillage are discussed. Finally, the soil databases available to assess worldwide soil resources are presented and discussed.

Scientific progress is based ultimately on unification rather than fragmentation of knowledge

F.C. Kafatos and T. Eisner

OIL IS A DYNAMIC SYSTEM in which minerals constantly interact with organic matter and microorganisms. Minerals, organic components, and microorganisms profoundly affect the physical, chemical, and biological properties and processes of terrestrial systems. However, in soil environments physical, chemical, and biological processes are not independent processes but rather interactive processes. Soils can be defined as complex interactive biogeochemical reactors, reservoirs of organisms (mainly microorganisms), and the major compartment of the terrestrial ecosystems under the influence of anthropogenic activities. To improve our scientific knowledge on soil resources and also its application to remediation and long-term management, it is of major importance and interest to study soil organization and function not only through the subdisciplines of soil sciences but also through interactive approaches. The study of interactions between soil constituents and soil organisms has to be considered at different scales, namely, from the molecular level to field/landscape systems and

is, indeed, essential to stimulating further research to uncover the dynamics and mechanisms of soil processes. Therefore, a new Commission 2.5 "Soil Physical/Chemical/Biological Interfacial Reactions" was created within the structure of the International Union of Soil Sciences in 2004. The major goal of Commission 2.5 is to better integrate the four subdisciplines of soil science (soil physics, soil chemistry, soil biology, and soil mineralogy) and to encourage interdisciplinary research. In fact, only by recognizing the complexity of terrestrial systems, it is possible to develop major advances in the understanding of problems related to soil. The fundamental interactive soil processes have enormous impacts on ecosystem productivity, services, integrity, and human welfare. Physical-chemicalbiological interfacial interactions govern weathering transformations of minerals; storage and turnover of organic matter; enzymatic activities; the structure, dynamics, and activities of microorganisms; porosity formation and structural stability of aggregates; and biogeochemical transformations and transport of chemical and biological components at different temporal and spatial scales.

This part includes discussions on advances in the employment of synchrotron to elucidate interfacial reactions involving nutrients and pollutants (Chapter 1); in describing the interactions of clay-size minerals in soil with natural organic matter, and the effects of these interactions on some soil properties and functions (Chapter 2); in explaining what makes nanomaterials unique, in providing insight into the special behaviors of nanomaterials, and in highlighting how the soil science community can both benefit from and contribute to nanoscale environmental

research (Chapter 3); in describing the impacts of environmental nanoparticles on chemical, biological, and hydrological processes in terrestrial ecosystems (Chapter 4); in explaining the effects of the soil components on the performance and efficiency of enzyme activities, the mechanisms involved in their interactions, the role of soil-bound enzymes from an ecological point of view, as well as their potential for practical purposes (Chapter 5). Furthermore, this part presents issues on the soil physical, chemical, and interfacial processes in the rhizosphere (Chapter 6) and soil mineralogical, physicochemical, and (micro)biological interactions on carbon turnover and sequestration (Chapter 7); on the transformation of metals and metalloids (Chapter 8);

on the fate of anthropogenic organic pollutants (Chapter 9); and on the transport of nutrients and pollutants (Chapter 10).

I am grateful to the authors who have contributed chapters to this part. Appreciation is extended to the external referees who have provided invaluable critical inputs to maintain the quality of this part.

This part is dedicated to Dr. P.M. Huang. At the time of his death, he was the editor in chief of the *Handbook of Soil Science* and editor of this part. Dr. Huang leaves to us a great scientific patrimony. We must always remember, particularly the youngest soil scientists, his ideas and suggestions, which were often ahead of their times, in the years to come.

1.1 Introduction

It has become increasingly recognized that to accurately predict and model fate/transport, toxicity, speciation (form of), bio-availability, and risk assessment of plant nutrients, toxic metals, oxyanions, radionuclides, and organic chemicals in the Earth's critical zone, we must have fundamental information at multiple spatial and temporal scales, and our research efforts must be multidisciplinary and interdisciplinary (Figure 1.1).

With the advent of state-of-the-art analytical techniques, particularly those that are synchrotron based, one can elucidate reaction mechanisms at small scales. This has been one of the major advances in soil and environmental sciences in the past two decades. The use of small-scale techniques in soil and environmental research has resulted in a new multidisciplinary field of study that soil scientists are actively involved in—molecular environmental science. Molecular environmental science can be defined as the study of the chemical and physical forms and distribution of contaminants in soils, sediments, waste materials, natural waters, and the atmosphere at the molecular level (Sparks, 2002).

There are a number of areas in environmental soil science where the application of molecular environmental science is propelling major frontiers. These include speciation of contaminants, which is essential for understanding release mechanisms,

spatial resolution, chemical transformations, toxicity, bioavailability, and ultimate impacts on human health; mechanisms of microbial transformations on mineral surfaces; phytoremediation; humic substance structure and chemistry; air and terrestrial emanated particulate reactivity and composition; soil structure; development of predictive models; effective remediation and waste management strategies; and risk assessment (Sparks, 2002).

The objective of this chapter is to discuss aspects of synchrotron-based radiation, with emphasis on x-ray techniques, and show their application to investigations involving important soil chemical processes and reactions involving soil components and heterogeneous systems such as soils and biosolids. Emphasis is placed on investigations of elements that can be studied in the hard x-ray region of the electromagnetic spectrum.

1.2 Molecular Environmental Soil Chemistry

1.2.1 Electromagnetic Spectrum of Light

The use of synchrotron light to understand mechanisms of soil chemical reactions and processes has revolutionized the field of environmental soil science. The electromagnetic spectrum of light is shown in Figure 1.2. Electromagnetic radiation has both

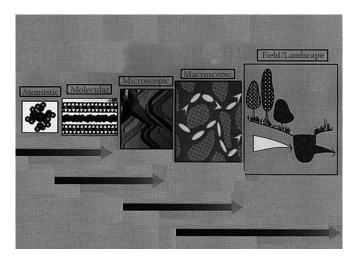

FIGURE 1.1 Illustration of the various spatial scales of interest to environmental scientists. (Reprinted with permission from Bertsch, P.M., and D.B. Hunter. 1998. Elucidating fundamental mechanisms in soil and environmental chemistry: The role of advanced analytical, spectroscopic, and microscopic methods, p. 103–122. *In* P.M. Huang (ed.) Future prospects for soil chemistry. SSSA, Madison, WI.)

particle and wave properties such that light at a particular wavelength corresponds to a particular scale of detection (O'Day, 1999). For example, longer wave radiation detects larger objects while shorter wave radiation detects smaller objects. Light employed to see an object must have a wavelength similar to the object's size. Light has wavelengths longer or shorter than visible light. On the longer side are radio waves, microwaves, and infrared radiation. Shorter wavelength light includes ultraviolet, x-rays, and gamma rays. The shorter the wavelength, the higher the frequency and

the more energetic or intense the light. Light generated at shorter wavelengths such as x-rays is not visible to the human eye and must be detected via special means (Sparks, 2002).

Each region of the spectrum is characterized by a range of wavelengths and photon energies that will determine the degree to which light will penetrate and interact with matter. At wavelengths from 10⁻⁷ to 10⁻¹⁰m, one can explore the atomic structure of solids, molecules, and biological structures. Atoms, molecules, proteins, chemical bond lengths, and minimum distances between atomic planes in crystals fall within this wavelength range and can be detected. The binding energies of many electrons in atoms, molecules, and biological systems fall in the range of photon energies between 10 and 10,000 eV. When absorbed by an atom, a photon causes an electron to separate from the atom or can cause the release or emission of other photons. By detecting and analyzing such electron or photon emissions, scientists can better understand the properties of a sample (Sparks, 2002).

1.2.2 Synchrotron Radiation

Intense light can be produced at a synchrotron facility. Synchrotron radiation is produced over a wide range of energies from the infrared region with energies less than 1 eV to the hard x-ray region with energies of 100 keV or more. There are more than 60 synchrotron light sources in over 30 countries (www.lightsources.org). In the United States, major facilities are found at National Laboratories. These include the National Synchrotron Light Source (NSLS) at Brookhaven National Laboratory, the Advanced Photon Source (APS) at Argonne National Laboratory (Figure 1.3), the Advanced Light Source

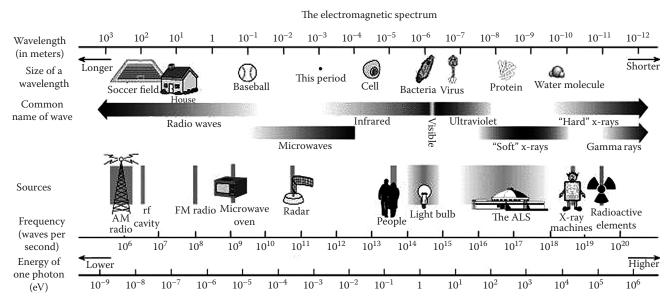

FIGURE 1.2 Electromagnetic spectrum of light covering a wide range of wavelengths and photon energies. Each region of the spectrum is characterized by a range of wavelengths and photon energies that will determine the degree to which light will penetrate and interact with matter. (Courtesy of the Advanced Light Source, Lawrence Berkeley National Laboratory, Berkeley, CA.)

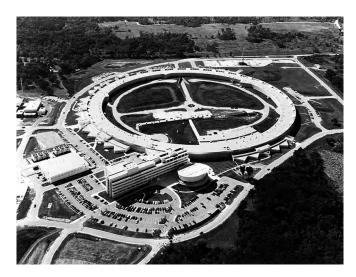

FIGURE 1.3 The Advanced Photon Source (APS), Argonne National Laboratory managed and operated by The University of Chicago for the U.S. Department of Energy under Contract No. W-31-109-ENG-38. (Courtesy of the Advanced Photon Source, Argonne National Laboratory, Argonne, IL.)

(ALS) at Lawrence Berkeley National Laboratory, and the Stanford Synchrotron Radiation Laboratory (SSRL) at Stanford University (Sparks, 2002). For more information on synchrotron user facilities around the globe and their capabilities in the geosciences, the reader should consult Sutton (2006).

Synchrotrons are large machines (Figure 1.4). The APS has a storage ring that is 1104 m in circumference (Figure 1.3). In the synchrotron, charged particles, either electrons or positrons, are injected into a ring-shaped chamber maintained at an ultrahigh

vacuum (UHV) (~10⁻⁹ Torr). The particles enter the ring by way of an injection magnet and then travel around the ring at or near the speed of light, steered by bending magnets. Additional magnets focus and shape the particle beam as it travels around the ring. Synchrotron radiation or light is emitted when the charged particles go through the bending magnets or through insertion devices, which are additional magnetic devices called wigglers or undulators inserted into straight sections of the ring. Beamlines allow the x-rays to enter experimental beamstations, which are shielded rooms that contain instrumentation for conducting scattering, spectroscopy, or imaging experiments (Schulze et al., 1999; Sparks, 2002; Brown et al., 2006).

Recently, several excellent reviews on the use of synchrotron techniques in the environmental sciences have been published. These reviews focused on the use of synchrotron techniques in low-temperature geochemistry and environmental science (Brown and Parks, 2001; Brown and Sturchio, 2002; Fenter et al., 2002), clay and soil science (Schulze et al., 1999; Kelly et al., 2008), and the study of heavy metals in the environment (Sparks, 2005a).

1.2.3 X-Ray Absorption Spectroscopy

One of the most widely used synchrotron-based spectroscopic techniques is x-ray absorption spectroscopy (XAS). XAS was developed in the early 1970s (Sayers et al., 1971). XAS can be used to study most elements in crystalline or noncrystalline solid, liquid, or gaseous states over a concentration range of a few parts per million to the pure element. It is also an in situ technique, which means that one can study reactions in the presence of water. This is a major advantage over many molecular scale techniques,

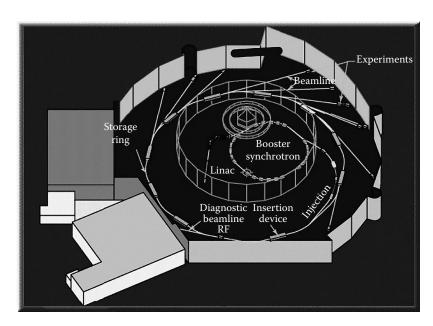

FIGURE 1.4 Schematic diagram of a synchrotron x-ray source. (Courtesy of the Advanced Light Source, Lawrence Berkeley National Laboratory, Berkeley, CA.)

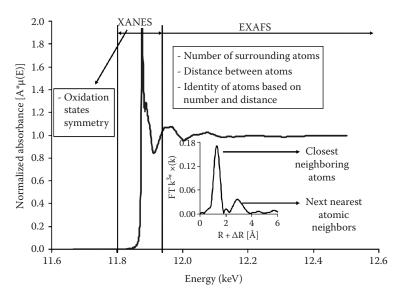

FIGURE 1.5 Energy regions of an XAS spectrum.

which are ex situ, often requiring drying of the sample material, placing it in a UHV, heating the sample, or employing particle bombardment. Such conditions can alter the sample, creating artifacts, and do not simulate most natural soil conditions.

One pitfall in the use of XAS and other synchrotron-based techniques, especially when employed at third- and fourth-generation light sources that have intense flux and brightness, is radiation damage. This can be especially problematic if one is investigating elements that are redox sensitive.

XAS is an element-specific method that yields information about the local structural and compositional environment of an absorbing atom. It "sees" only the two or three closest shells of neighbors around an absorbing atom (<6 Å) due to the short electron mean free path in most substances. Using XAS, one can ascertain important soil chemical information such as the oxidation state, information on next nearest neighbors, bond distances (accurate to ± 0.02 Å), and coordination numbers (accurate to $\pm 15\%$ –20%) (Brown et al., 1995; Sparks, 2002).

An XAS experiment, which results in a spectrum (Figure 1.5), consists of exposing a sample to an incident monochromatic beam of synchrotron x-rays, scanned over a range of energies below and above the absorption edge (K, L, M) of the element of interest. When x-rays interact with matter, a number of processes can occur: X-ray scattering production of optical photons, production of photoelectrons and Auger electrons, production of fluorescence x-ray photons, and positron–electron pair production (Sparks, 2002).

The energy region extending from just below to about 50 eV above the absorption edge is the XANES (x-ray absorption near edge structure) portion of the spectrum (Figure 1.5). Fingerprint information (e.g., oxidation states) can be gleaned from this region of the XAS spectrum. The XANES region of the spectrum, although not providing as much quantitative information as the extended x-ray absorption fine structure (EXAFS) region, is often more intense and can provide qualitative or

semiquantitative information on the oxidation state of the measured element (Brown et al., 1995). Such information can be obtained by comparing the features of the XANES spectrum of the sample with features of XANES spectra for well-characterized reference compounds (Figure 1.6). Some species, such as Cr,

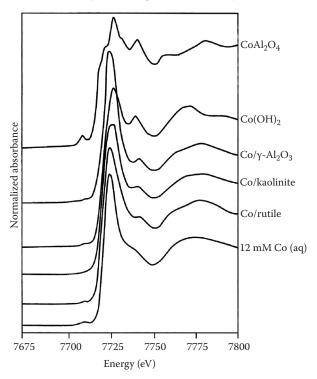

FIGURE 1.6 Co K-edge XANES spectra of $CoAl_2O_4$ spinel, crystalline $Co(OH)_2$, three samples with aqueous Co(II) sorbed on γ -Al $_2O_3$, kaolinite [Si $_4$ Al $_4O_{10}(OH)_8$], and rutile (TiO $_2$), and a 12 mM aqueous $Co(NO_3)_2$ solution. (Reprinted by permission from Macmillan Publishers Ltd., Chisholm-Brause, C.J., P.A. O'Day, G.E. Brown, Jr., and G.A. Parks. 1990. Evidence for multinuclear metal-ion complexes at solid/water interfaces from X-ray absorption spectroscopy. Nature 348:528–530.)

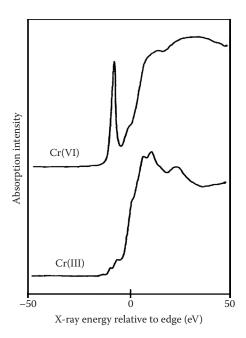

FIGURE 1.7 Comparison of XANES spectra for Cr(III) and Cr(VI). (Reprinted with permission from Fendorf, S.E., G.M. Lamble, M.G. Stapleton, M.J. Kelley, and D.L. Sparks. 1994. Mechanisms of chromium (III) sorption on silica: 1. Cr(III) surface structure derived by extended x-ray absorption fine structure spectroscopy. Environ. Sci. Technol. 28:284–289. Copyright (1994) American Chemical Society).

yield remarkably different, easily recognizable XANES spectra (Figure 1.7). In Figure 1.7, it is easy to differentiate Cr(III) from Cr(VI) as there is a prominent preedge feature for Cr(VI) that is absent for Cr(III) (Sparks, 2002).

The energy region from 50 to 1000 eV above the absorption edge is the EXAFS portion of the spectrum (Figure 1.5). Analysis of an EXAFS spectrum is illustrated in Figure 1.8 and involves extracting structural parameters including interatomic distances (R), coordination numbers (CN), and identity of first, second, and more distant shells of neighbors around an absorber (Brown et al., 1995; Sparks, 2002).

The fine structure refers to the small oscillations in the extended portion of the XAS spectra caused by the interaction between outgoing photoelectrons and those backscattered off atoms neighboring the central absorbing atom. In order to extract information from this region, mathematical procedures must be performed to isolate and amplify these subtle oscillations. The spectrum is first converted from electron volts to photoelectron wave numbers (k in Å-1) based on a specified value for E_0 , the threshold energy for x-ray absorption. The oscillatory fine structure data are then isolated by subtracting a background function representing one atomic x-ray absorption event. The resulting function $[\chi(k)]$ is often weighted, most commonly by the square or cube of the wave number $[\chi(k)^*k^2$ or $\chi(k)^*k^3]$, to amplify the dampened oscillations occurring at higher k. These data can then be transformed using Fourier filtering methods to separate the contributions from the different atoms surrounding the absorbing atom, resulting in a radial structure function

(RSF) with peaks representative of the location and distance of the neighboring atoms (McNear et al., 2005b). To derive accurate structural parameters, it is also necessary to obtain experimental EXAFS data for model or reference compounds that have known structures and contain the absorber and nearest neighbors' backscatters of interest.

XAS experiments can be conducted in several modes that differ in the type of detected particle: transmission (x-rays transmitted through the sample), fluorescence (fluorescent x-rays emitted due to absorption of the incident x-ray beam), or electron yield (emitted photons). In a transmission experiment, the incident (I_0) and transmitted (I_1) x-ray intensities are recorded as a function of increasing incident x-ray energy (E) to yield an absorption spectrum, which is plotted as $\ln (I_0/I_1)$ vs. E (in eV) (Figure 1.5). The relationship between these intensities and the linear absorption coefficient μ (in cm⁻¹) of a sample of thickness x (in cm) is $\ln (I_0/I_1) = \mu x$. In a fluorescence experiment, the x-ray fluorescence from the sample, I_P can be measured and ratioed with I_0 as I_f/I_0 , which is proportional to μ for dilute samples. Fluorescence methods are preferred for elements that may be contained in low concentrations on mineral surfaces (Brown et al., 1995; Sparks, 2002).

Additional detail on XAS principles, methodology, sample preparation, and data analyses can be found in a number of excellent sources (Brown, 1990; Manceau et al., 1992; Fendorf et al., 1994; Schulze and Bertsch, 1995; O'Day, 1999; Bertsch and Hunter, 2001; Brown and Parks, 2001; Brown and Sturchio, 2002; Fenter et al., 2002; Kelly et al., 2008).

1.2.4 Complementary/Alternative Synchrotron-Based Techniques

Soil scientists have recently begun employing variations on traditional bulk XAS including bulk and microfocused synchrotron x-ray diffraction (S-XRD and μ -XRD, respectively) and microfocused-XANES and EXAFS spectroscopies (μ -XANES and μ -EXAFS, respectively). Microfocused diffraction and spectroscopic techniques are often coupled with microfocused x-ray fluorescence (μ -XRF) mapping to determine the areas of interest to be analyzed (Brown and Sturchio, 2002; Ginder-Vogel and Sparks, 2010). Another variation is quick-scanning XAS, which allows the collection of a complete XANES or EXAFS spectrum in as little as 300 ms (Dent, 2002).

1.2.4.1 Synchrotron X-Ray Diffraction

X-ray diffraction (XRD) is one of the most fundamental techniques used in the characterization and identification of crystalline materials in soils and sediments. Conventional (i.e., lab-based) XRD uses monochromatic x-rays generated when high voltage is applied to an anode, generally Al or Cu. Conventional XRD is generally limited to crystalline materials; additionally, conventional XRD is time-consuming and requires a large sample volume. The low flux of lab-based x-ray sources generally limits the geometry of the diffractometer, which requires data collection of reflected x-rays, rather than

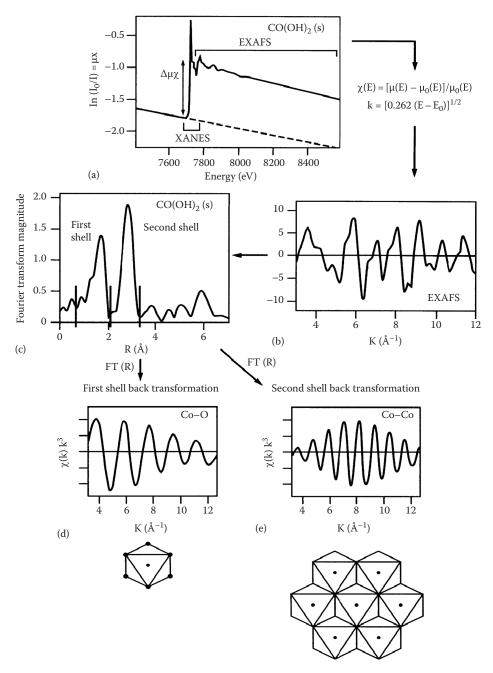

FIGURE 1.8 Illustration of the steps involved in analysis of an EXAFS spectrum, using the Co K-XAS of solid Co(OH)₂ as an example. (a,b) Subtraction of background (dashed line in EXAFS spectrum) yields the EXAFS function $(\chi(k) \times k^3)$ vs. k (\mathring{A}^{-1}) . (c) Fourier transformation of the background-subtracted EXAFS function yields an RSF (Fourier transform magnitude vs. R (\mathring{A})), which contains peaks at different distances associated with various shells of neighboring atoms around Co. (d) Fourier filtering of the different shells and back Fourier transformation yield the frequency contribution of each neighboring shell of atoms around Co. In this example, the first peak (d) in the RSF is caused by backscattering of the photoelectron from six nearest-neighbor O atoms at 2.08 Å from Co and the second peak (e) by backscattering from six second neighbor Co atoms at 3.17 Å from the central Co atom. (Reprinted with kind permission from Springer Science+Business Media: Brown, G.E., Jr., G.A. Parks, and P.A. O'Day. 1995. Sorption at mineral-water interfaces: Macroscopic and microscopic perspectives, p. 129–183. *In* D.J. Vaughan and R.A.D. Pattrick (eds.) Mineral surfaces. Chapman & Hall, London, U.K.)

transmitted x-rays, making analysis of hydrated samples quite difficult. However, S-XRD circumvents many of the limitations of conventional x-ray diffraction. It offers exceptional resolution and sensitivity, even on very small samples. This permits the identification and quantification of trace phases, which are not possible using conventional x-ray sources. Additionally, amorphous materials, thin films, and hydrated samples can be analyzed, due to the high flux of synchrotron x-ray sources and specialized instrumental configuration. With the use of area detectors or CCD cameras, similar to protein crystallography

beamlines, it is possible to collect a single XRD pattern in a matter of seconds, allowing for the monitoring of reactions in specially constructed XRD mounts. Finally, S-XRD data can be collected over a very large angular range, which allows analysis of the data using Rietveld refinements. These refinements can then be used to determine unit cell parameters and site occupancy (Ginder-Vogel and Sparks, 2010).

1.2.4.2 Microfocused XAS and XRF

With the advent of third-generation synchrotron light sources that have higher flux and higher brightness x-rays, together with stateof-the-art detectors and better beamline optics, microfocused beams for spectromicroscopy and imaging are available to study heterogeneous natural systems such as soils, biosolids, and plants. With these techniques, one can study areas of square microns and focus the beam to spatial resolutions of less than 5 µm, enabling one to directly speciate contaminants in heterogeneous materials. This has been a major advance in the past 10 years, and coupled with μ -XRF, one can also determine the distribution and association of metals and oxyanions in complex natural systems. Although bulk XAS can and should be used to provide the major species that are found in such systems, one often needs to couple these studies with μ-XAFS and μ-XRF investigations to more precisely quantify major species and determine associations and distributions of elements over small areas. There are several disadvantages in using bulk XAS to speciate contaminants in heterogeneous systems such as soils. Soils are complex and contain an array of inorganic and organic components, including humic substances, clay minerals, metal hydr(oxides), macro- and micropores, and microorganisms, all closely associated with each other. In such systems,

some microenvironments contain isolated phases in higher concentrations relative to the average in the total (bulk) matrix. For example, the oxides, minerals, and microorganisms in the rhizosphere have quite a different chemical environment compared to the bulk soil. These phases may be very reactive and important in the partitioning of metals but may be overlooked using other analytical techniques that measure the average of all phases. Standard bulk XAS techniques probe an area of several square millimeters and provide information on the average local chemical environment. Consequently, where more than one type of surface species is present, bulk XAS will detect only the primary (or average) type of surface product/species in the bulk sample. However, the most reactive sites in soils have particle sizes in the micrometer range, and metal speciation may vary over regions of a few 100 µm². The existence of multiple species in soils results in overlapping atomic shells, and it is difficult to ascertain the precise metal speciation with bulk XAS. Minor metal-bearing phases, even though they may constitute the most reactive or significant species, may not be successfully detected with bulk analyses (McNear et al., 2005b).

Some excellent reviews have appeared on the application of μ -XAS and μ -XRF to speciate contaminants in heterogeneous systems (Bertsch and Hunter, 1998; Hunter and Bertsch, 1998; Bertsch and Seaman, 1999; Manceau et al., 2002). A number of investigations have appeared over the past 10 years on the speciation of metals and oxyanions in soils, plants, biosolids, and fly ash (see references in Brown and Sturchio, 2002; Ginder-Vogel and Sparks, 2010).

A typical μ -XAS experiment (Figure 1.9) begins by collecting x-ray fluorescence elemental maps from which metal correlations can be observed. From these maps, regions of interest

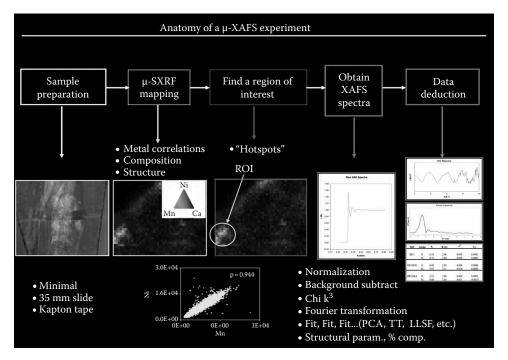

FIGURE 1.9 Anatomy of a μ -XAFS experiment. (Reprinted from McNear, D.H., Jr., R. Tappero, and D.L. Sparks. 2005b. Shining light on metals in the environment. Elements 1:211–216. With permission from Minerological Society of America.)

(i.e., hotspots) are selected and further probed using the microfocused x-ray beam. Analysis of XAS spectra collected from multicomponent systems cannot rely on traditional fitting procedures in which the spectra are broken down into individual atomic shells. Thus, to determine the species present within a mixed system, a dataset of spectra from multiple spots throughout a sample are analyzed statistically using principal component analysis (PCA). The PCA technique determines if the dataset can be described as weighted sums of a smaller number of components, which would be the case if each spot in the dataset comprises a smaller number of distinct compounds. Target transformation (TT) is then used to identify the components by taking a spectrum of a known reference compound and mathematically removing from the spectrum anything that does not look like the principal components identified by PCA. If minimal information has to be removed from the known reference spectrum, then one can conclude it is most likely present in the sample. After the contributing standard phases are identified, linear least squares fitting (LLSF) is used to determine the amount (%) of each standard species within the individual sample spectrum making up the dataset. The accuracy of this fitting approach is dependent on the data quality, the completeness of the standard dataset, and the range over which the data were fit. Additional and more thorough discussions on µ-XAS applications and methods of data collection and analysis for contaminants in heterogeneous systems can be found in Bertsch and Hunter (2001), Manceau et al. (2002), and McNear et al. (2005b).

1.2.4.3 Quick XAS

In soil environments, chemical reactions at the mineral/water interface occur over a range of temporal scales, ranging from microseconds to years. Many important processes (e.g., adsorption, oxidation-reduction, precipitation) occurring at mineral surfaces are characterized by a rapid initial reaction on a timescale of milliseconds to minutes (Scheidegger and Sparks, 1996). Knowledge of these initial reaction rates is critical to determining chemical kinetic rate constants and reaction mechanisms, both of which are necessary to understand environmental chemical processes. Kinetic measurements, using traditional techniques, such as batch or stirred-flow techniques, typically yield only a few data points during the initial phases of the reaction and cannot capture important reaction rates on second and slower timescales. Chemical relaxation techniques such as pressure jump (p-jump) and concentration jump (c-jump such as stopped flow) allow rapid data collection on timescales of milliseconds. However, rate "constants" are calculated from linearized rate equations that include parameters that were determined from equilibrium and modeling studies. Consequently, the rate "constants" are not directly determined (Ginder-Vogel et al., 2009; Ginder-Vogel and Sparks, 2010).

Direct, in situ, molecular-scale measurement of rapid reactions has been quite limited until recently. Fendorf et al. (1993) used stop-flow electron paramagnetic resonance spectroscopy to measure Mn(II) sorption to birnessite (δ -MnO₂) on a timescale of milliseconds. More recently, Parikh et al. (2008) used in situ,

Fourier Transform infrared (FTIR) spectroscopy to measure As(III) oxidation rates by hydrous manganese(IV) oxide (HMO) at a timescale of ~2.5 s. However, both of these techniques suffer from limitations. EPR can only be used to measure EPR active nuclei, whereas FTIR requires both IR active functional groups and relatively high concentrations of the reactants being examined (Parikh et al., 2008).

Quick-scanning x-ray absorption spectroscopy (QXAS) overcomes both of these limitations. Depending on beamline instrumentation and flux, QXAS can be used to probe most of the atoms in the periodic table and to relatively low concentrations (Khalid et al., 2010). The majority of the quick-scanning beamlines in the world collect a complete EXAFS scan in ~1 min, by slewing the monochromator from low energy to high energy and repeating the process (Mitsunobu et al., 2006). An alternative method for rapidly collecting EXAFS data is to perform energydispersive measurements; however, this technique generally suffers from poor sensitivity (Dent, 2002). However, using a unique, cam-operated, continuous-scanning setup at beamline X18B at the NSLS, it is possible to collect XANES and EXAFS spectra as the monochromator travels both up and down in energy (Khalid et al., 2010). Combined with electronics that collect 2000 data points per second, this unique setup allows the collection of a single EXAFS scan in as little as 100 ms. Landrot et al. (2010) used this beamline to examine the kinetics of Cr(III) oxidation by HMO, employing XANES spectroscopy, with a time resolution of 2s, while Ginder-Vogel et al. (2009) examined the mechanism of As(III) oxidation at the HMO mineral surface, using EXAFS spectroscopy, at similar timescales.

1.3 Applications of Synchrotron-Based Techniques to Elucidate Soil Chemical Processes and Reactions

In situ (under natural conditions where water is present) molecular scale techniques, such as synchrotron-based XAS, XRF, XRD, and microtomography, have been widely used over the past 20 years to study metal(loid) and radionuclide sorption phenomena at the mineral/water interface and to determine the chemical form (speciation) and distribution of environmental contaminants in heterogeneous natural materials, such as minerals, soils, plants, and terrestrial-based airborne particulates. Arguably, they have revolutionized many fields, including soil science, geochemistry, and the environmental sciences.

Synchrotron light sources were first available to general users in 1974. The first published study that employed XAS to directly delineate the type of surface complexes formed at mineral/water interfaces was the seminal research of Hayes et al. (1987). Studying selenite and selenate sorption at the goethite/water interface, selenite was observed to primarily form an inner-sphere surface complex, whereas selenate predominantly formed an outer-sphere complex. This was the first direct confirmation that indeed innerand outer-sphere surface complexes, first proposed by Werner Stumm and coworkers, form on natural mineral surfaces.

1.3.1 Adsorption of Metals and Oxyanions on Soil Components

Since 1987, hundreds of studies using bulk XAS (Sparks, 1995; Brown and Parks, 2001; Brown and Sturchio, 2002; Sparks, 2005b; Brown et al., 2006) have provided extensive information on metal and oxyanion sorption on metal hydr(oxides), clay minerals, humic substances, and other natural materials, including structure, stoichiometry, attachment geometry (inner- vs. outer-sphere, monodentate vs. bidentate or tridentate), the presence of multinuclear complexes and precipitate phases, and the presence of ternary surface complexes when complexing ligands are present in solution (Brown and Parks, 2001; Brown and Sturchio, 2002; Sparks, 2005b). The type of surface complexes on clay minerals and metal-(oxyhydr)oxides that occur with low atomic number elements, such as Al, B, Ca, Mg, S, and Si, are not easy to ascertain using XAS under in situ conditions. However, major advances are being made in the area of soft x-ray XAS spectroscopy that will enable one to directly determine the types of surface complexes that form with these metal(loids) (Ginder-Vogel and Sparks, 2010).

Based on molecular scale studies, including many using XAS, one can predict that alkaline earth cations, Mg^{2+} , Ca^{2+} , Sr^{2+} , and Ba^{2+} primarily form outer-sphere complexes, whereas the divalent first-row transition metal cations Mn^{2+} , Fe^{2+} , Co^{2+} , Ni^{2+} , Cu^{2+} , and Zn^{2+} and the divalent heavy metal cations such as Cd^{2+} , Hg^{2+} , and Pb^{2+} primarily form inner-sphere complexes. At higher metal loadings and pHs, sorption of metals such as Co, Cr, Ni, and Zn on phyllosilicates and metal-(oxyhydr) oxides can result in the formation of surface precipitates. The formation of these multinuclear and precipitate phases will be discussed in more detail later.

Although there are currently experimental limitations to using in situ molecular scale techniques to directly determine the type of surface complexes that the anions NO₃⁻, Cl⁻, and ClO₄⁻ form on mineral surfaces, one can propose that they are sorbed as outer-sphere complexes and sorbed on surfaces that exhibit a positive charge. Some researchers have also concluded that SO₄²⁻ (Zhang and Sparks, 1990) can be sorbed as an outer-sphere complex; however, there is other evidence that SO₄²⁻ can also be sorbed as an inner-sphere complex (Manceau and Charlet, 1994). There is direct spectroscopic evidence to show that selenate can be sorbed as both an outer-sphere and an inner-sphere complex, depending on environmental factors (Hayes et al., 1987; Wijnja and Schulthess, 2000).

Most other anions such as molybdate, arsenate, arsenite, selenite, phosphate, and silicate appear to be strongly sorbed as inner-sphere complexes, and sorption occurs through a ligand exchange mechanism. The sorption maximum is often insensitive to ionic strength changes. Sorption of anions via ligand exchange results in a shift in the point of zero charge of the sorbent to a more acidic value (Sparks, 2002, 2005b).

One must be aware that bulk XAS probes an area of several square millimeters and provides information on the average local chemical environment of a surface. Thus, where more than one type of surface species is present, bulk XAS will detect only the primary (or average) type of surface product/species in the bulk sample (i.e., sums over all geometric configurations of the target atom). Consequently, although it may be concluded that the primary surface complex is inner sphere, this does not mean that outer-sphere complexation is not occurring. Recently, through the use of x-ray scattering measurements to study metal(loid) binding on single crystal surfaces, Catalano et al. (2008) showed that arsenate surface complexation was bimodal, with adsorption occurring simultaneously as inner- and outer-sphere species.

Environmental factors such as pH, surface loading, ionic strength, type of sorbent, and time also affect the type of sorption complex or product. An example of this can be found in the research of Strawn and Sparks (1999) who investigated Pb sorption on montmorillonite over an ionic strength (I) of 0.006-0.1 and a pH range of 4.48-6.77. Employing XAS analysis, at a pH of 4.48 and I of 0.006, it was determined that outer-sphere complexation on basal planes in the interlayer regions of the montmorillonite predominated. At a pH of 6.77 and I of 0.1, inner-sphere complexation on edge sites of montmorillonite was most prominent, and at pH of 6.76, I of 0.006, pH of 6.31, and I of 0.1, both inner- and outer-sphere complexation occurred. These data are consistent with other findings that inner-sphere complexation is favored at higher pH and ionic strength. Clearly, there is a continuum of adsorption complexes that can exist in soils (Sparks, 2002, 2005b, Ginder-Vogel and Sparks, 2010).

1.3.2 Metal(loid) Surface Precipitation/ Dissolution

As the amount of metal cation or anion sorbed on a surface (surface coverage or loading, which is affected by the pH at which sorption occurs) increases, sorption can proceed from mononuclear adsorption to surface precipitation (a three-dimensional phase). There are several types of surface precipitates. They can arise via polymeric metal complexes (dimers, trimers, etc.) that form on mineral surfaces and via the sorption of aqueous polymers (Chisholm-Brause et al., 1990). Homogeneous precipitates can form on a surface when the solution becomes saturated and the surface acts as a nucleation site. When adsorption attains monolayer coverage, sorption continues on the newly created sites, causing a precipitate on the surface (Farley et al., 1985; Sposito, 1986; Chisholm-Brause et al., 1990; McBride, 1991; O'Day et al., 1994). When the precipitate consists of chemical species derived from both the aqueous solution and dissolution of the mineral, it is referred to as a coprecipitate. The composition of the coprecipitate varies between that of the original solid and a pure precipitate of the sorbing metal. The ionic radius of the sorbing metal and sorbent ions must be similar for coprecipitates to form. Thus Co(II), Mn(II), Ni(II), and Zn(II) form coprecipitates on sorbents containing Al(III) and Si(IV) but not Pb(II), which is considerably larger (1.20 Å). Coprecipitate formation is most limited by the rate of mineral dissolution rather than the lack of thermodynamic favorability (McBride, 1994; Scheidegger et al., 1998). If the formation of a precipitate occurs under solution conditions that would, in the absence of a sorbent, be undersaturated with respect to any known solid phase, this is referred to as surface-induced precipitation (Towle et al., 1997; Sparks, 2005a; Borda and Sparks, 2008; Ginder-Vogel and Sparks, 2010).

Thus, there is often a continuum between surface complexation (adsorption) and surface precipitation. At low surface coverages, surface complexation (e.g., outer- and inner-sphere adsorption) tends to dominate. As surface loadings increase, nucleation occurs and results in the formation of distinct entities or aggregates on the surface. As surface loadings increase further, surface precipitation becomes the dominant mechanism.

Using in situ bulk XAS, it has been shown by a number of scientists that multinuclear metal hydroxide complexes and surface precipitates of Co2+, Cr3+, Cu2+, Ni2+, and Pb2+ can form on metal oxides, phyllosilicates, soil clays, and soils (Chisholm-Brause et al., 1990, 1994; Roe et al., 1991; Charlet and Manceau, 1992; Fendorf et al., 1994; O'Day et al., 1994; Bargar et al., 1995; Papelis and Hayes, 1996; Scheidegger et al., 1996a, 1996b, 1997, 1998; Towle et al., 1997; Elzinga and Sparks, 1999; Roberts et al., 1999; Thompson et al., 1999a, 1999b; Ford and Sparks, 2000; Scheckel and Sparks, 2001b). These metal hydroxide phases occur at metal loadings below theoretical monolayer coverage and in a pH range well below the pH where the formation of metal hydroxide precipitates would be expected, according to the thermodynamic solubility product (Scheidegger and Sparks, 1996; Sparks, 2002, 2005b; Borda and Sparks, 2008; Ginder-Vogel and Sparks, 2010).

Scheidegger et al. (1997) were the first to show that sorption of metals, such as Ni, on an array of phyllosilicates and Al oxide, could result in the formation of mixed metal-Al hydroxide surface precipitates, which appear to be coprecipitates. The precipitate phase shares structural features common to the hydrotalcite group of minerals and the layered double hydroxides (LDH) observed in catalyst synthesis. The LDH structure is built of stacked sheets of edge-sharing metal octahedra, containing divalent and trivalent metal ions separated by anions between the interlayer spaces (Figure 1.10). The general structural formula can be expressed as $[Me^{2+}Me_x^{3+}(OH)_2]^{x+} \cdot [(x/n)A^n - mH_2O]$, where, for example, Me²⁺ could be Mg(II), Ni(II), Co(II), Zn(II), Mn(II), and Fe(II) and Me3+ is Al(III), Fe(III), and Cr(III) (Towle et al., 1997). The LDH structure exhibits a net positive charge x per formula unit, which is balanced by an equal negative charge from interlayer anions An-, such as Cl-, Br-, I-, NO₃-, OH-, ClO₄-, and CO_3^{2-} ; water molecules occupy the remaining interlayer space (Taylor, 1984). The minerals takovite, Ni₆ Al₂(OH)₁₆ CO₃·H₂O, and hydrotalcite, Mg₆ Al₂(OH)₁₆ CO₃ · H₂O, are among the most common natural mixed-cation hydroxide compounds containing Al (Taylor, 1984; Sparks, 2005b; Borda and Sparks, 2008). Recently, Livi et al. (2009), using an array of microscopic techniques including analytical electron microscopy, high resolution transmission electron microscopy, and powder x-ray diffraction, conducted studies to elucidate the nature of

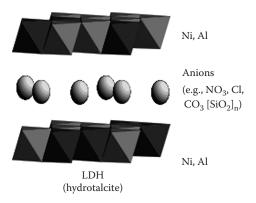

FIGURE 1.10 Structure of Ni–Al LDH showing brucite-like octahedral layers in which Al substitutes for Ni, creating a net positive charge balanced by hydrated anions in the interlayer space. (Reprinted from Scheinost, A.C., R.G. Ford, and D.L. Sparks. 1999. The role of Al in the formation of secondary Ni precipitates on pyrophyllite, gibbsite, talc, and amorphous silica: A DRS study. Geochim. Cosmochim. Acta 63:3193–3203, Copyright 1999. With permission from Elsevier.)

Ni hydroxide precipitates, using the same environmental conditions employed by Scheidegger et al. (1996b, 1997) and reaction times ranging from 1 h to 5 years. Although the precipitate phase had a bonding environment similar to Ni-Al LDH, the precipitate was amorphous.

Mixed Co–Al and Zn–Al hydroxide surface precipitates can also form on aluminum-bearing metal oxides and phyllosilicates (Towle et al., 1997; Thompson et al., 1999a, 1999b; Ford and Sparks, 2000). This is not surprising, as Co²⁺, Zn²⁺, and Ni²⁺ all have similar radii to Al³⁺, enhancing substitution in the mineral structure and formation of a coprecipitate. However, surface precipitates have not been observed with Pb²⁺, as Pb²⁺ is too large to substitute for Al³⁺ in mineral structures (Sparks, 2002, 2005b; Borda and Sparks, 2008; Ginder-Vogel and Sparks, 2010).

The mechanism for the formation of metal hydroxide surface precipitates is not clearly understood. It is clear that the type of metal ion determines whether metal hydroxide surface precipitates form, and the type of surface precipitate formed, that is, metal hydroxide or mixed metal hydroxide, is dependent on the sorbent type. Additionally, the reaction pH, which controls the degree of metal loading, is also a major factor in determining the formation of metal hydroxide precipitates. Sparks and his group have shown that below pH 6.5, metal hydroxide precipitates do not form on mineral surfaces or in soils in laboratory studies (Elzinga and Sparks, 1999, 2001; Roberts et al., 1999, 2003).

The formation of metal hydroxide surface precipitates appears to be an important way to sequester metals. As the surface precipitates age, metal release is greatly reduced (Figure 1.11). Thus, the metals are less prone to leaching and being taken up by plants and microbes. Peltier et al. (2010) reacted three soils of varying mineralogy and organic matter content with 3 mM Ni at two pHs, 6 and 7.5, and evaluated Ni bioavailability using a biosensor. At pH 6, where surface precipitates did not form, most of the Ni was bioavailable. However, at pH 7.5, where precipitates

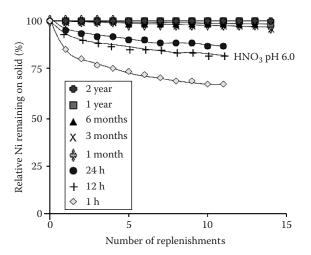

FIGURE 1.11 Dissolution of Ni from surface precipitates formed on pyrophyllite at residence times of 1h to 2 years. The figure shows the relative amount of Ni²⁺ remaining on the pyrophyllite surface following extraction for a 24h period (each replenishment represents a 24h extraction) with HNO₃ at pH 6.0. (Reprinted from Scheckel, K.G., and D.L. Sparks. 2001a. Dissolution kinetics of nickel surface precipitates on clay mineral and oxide surfaces. Soil Sci. Soc. Am. J. 65:685–694. With permission from Soil Science Society of America.)

were observed to form from XAS analyses, Ni bioavailability was markedly reduced.

The decrease in metal release and bioavailability is linked to the increasing silication of the interlayer of the LDH phases with increased residence time, resulting in a mineral transformation from a LDH phase to a precursor phyllosilicate surface precipitate (Ford et al., 1999; Ford and Sparks, 2000). The mechanism for this transformation is thought to be the diffusion of Si, originating from weathering of the sorbent, into the interlayer space of the LDH, replacing the anions such as NO₃⁻. Polymerization and condensation of the interlayer Si slowly transforms the LDH into a precursor metal-Al phyllosilicate. The metal stabilization that occurs in surface precipitates on Al-free sorbents (e.g., talc) may be due to Ostwald ripening, resulting in increased crystallization; however, as noted earlier, microscopic analyses have shown that Ni-Al LDH phases are amorphous (Livi et al., 2009). Peltier et al. (2006), using acid-solution calorimetry and results from previous calorimetry studies, showed that the enthalpy of formation of LDH phases is more exothermic, indicating great stability, in the order of Cl < NO₃ < SO₄ < CO₃ < Si of interlayer anionic composition, and that LDH phases were much more stable than a Ni(OH), phase.

In short, with time, metal sorption on soil minerals can often result in a continuum of processes, from adsorption to precipitation to solid-phase transformation, particularly in the case of certain metals, such as Co²⁺, Ni²⁺, and Zn²⁺. The formation of metal surface precipitates could be an important mechanism for sequestering metals in soils, such that they are less mobile and bioavailable. Such products must be considered when modeling the fate and mobility of metals such as Co²⁺, Mn²⁺, Ni²⁺, and Zn²⁺ in soil and water environments (Sparks, 2002, 2005b; Borda and Sparks, 2008; Ginder-Vogel and Sparks, 2010).

1.3.3 Redox Reactions on Soil Components

The mobility and environmental threat of many contaminants and nutrients are determined in large part by their redox state and the redox conditions of the soil environments in which they exist. XAS is an ideal tool for determining the oxidation states of elements in complex environmental media including soils and sediments. A change in oxidation state of an element results in a change in the energy required to excite a core electron into the continuum, which manifests itself by a shift in the white-line position for an element and can be determined using XANES spectroscopy. In addition, a change in the element's local coordination environment occurs and is manifested in EXAFS spectra of the element. This is readily exemplified by the reduction of soluble U(VI)O₂²⁺ (and its various complexes) to $U(IV)O_2$, which results in the absorption edge shifting ~3 eV lower in energy (Figure 1.12). Additionally, the transition from the highly linear uranyl ion results in the loss of a large shoulder, due to multiple scattering, that immediately follows the white line (Figure 1.12) (Kelly et al., 2002, 2007, 2008; Ginder-Vogel et al., 2010).

In addition to uranium, XAS has been used to investigate metal and oxyanions cycling in many redox active systems (Fendorf et al., 1992, 2002; Bostick et al., 2002; Manning et al., 2002; Hansel et al., 2003a, 2003b, 2005; Webb et al., 2005; Bank et al., 2007; Ginder-Vogel and Fendorf, 2008). The primary elements of interest include environmentally predominant transition metals, such as iron and manganese, in addition to elements that exist in the environment primarily as oxyanions, such as arsenic, chromium, and selenium. Many of these redox reactions are driven by bacterial metabolism and result in the formation of

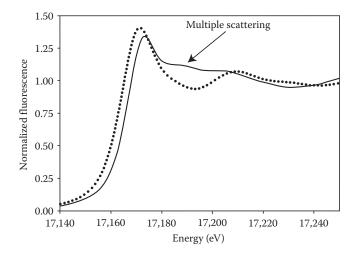

FIGURE 1.12 Uranium $L_{\rm III}$ -edge XANES spectra of uraninite (dotted) and uranyl nitrate hexahydrate (solid). The arrow indicates the contribution of multiple scattering from the uranyl moiety. (Reprinted from Ginder-Vogel, M., and S.E. Fendorf. 2008. Biogeochemical uranium redox transformation: Potential oxidants of uraninite, p. 293–320. *In* M.O. Barnett and D.B. Kent (eds.) Adsorption of metals by geomedia II: Variables, mechanisms, and model applications. Elsevier, Amsterdam, the Netherlands. With permission from Elsevier.)

hydrated mineral phases, making in situ (i.e., wet) analysis critical to determining the operative redox pathways (Ginder-Vogel and Sparks, 2010).

1.3.4 Transition-Metal Oxides

The environmental prevalence of iron and manganese oxides, hydroxides, and oxyhydroxides [(hydr)oxides], coupled with the large quantity of their highly reactive surface area, makes them an important pool of reactivity, with regard to contaminant and nutrient absorption and redox transformation. However, their reactivity, in terms of both sorption and redox chemistry, is radically altered by changes in redox conditions, especially as they impact mineralogy and surface chemistry of iron and manganese oxide phases (Ginder-Vogel and Sparks, 2010).

Ferrihydrite, a poorly crystalline Fe(III) (hydr)oxide, is often found in soils and sediments, oscillating between reducing and oxidizing conditions. Due to its high surface area and intrinsic reactivity, ferrihydrite serves as a critical sink for contaminants (e.g., As and U) and nutrients (e.g., P); however, until recently, the impact of reducing conditions on the evolution of Fe(III) mineral mineralogy and its subsequent ability to retain and interact with contaminants and nutrients has been poorly understood. XAS, coupled with other advanced analytical techniques, has played a key role in furthering our understanding of this important environmental process. Ferrihydrite is considered the most bioavailable Fe(III) (hydr)oxide for dissimilatory metal reducing bacteria, which couple the oxidation of organic matter and H2 to the reduction of Fe(III) and are ubiquitous in saturated soils and sediments. Upon dissimilatory metal reduction, the production of Fe(II) may result either in Fe(III) mineral dissolution or the rapid transformation of poorly crystalline Fe(III) (hydr)oxides into more crystalline and/or mixed Fe(II)/Fe(III) (hydr)oxides, dependent on the intensity of Fe(III) reduction (Ginder-Vogel and Sparks, 2010).

XAS has played a vital role in the identification and quantification of Fe (hydr)oxide mineralogy. In batch experiments using ferrihydrite, the solid phases formed during microbial iron reduction are dominated by the metabolic byproducts of Fe reduction, including ferrous iron and bicarbonate, and generate minerals rich in Fe(II) and bicarbonate, including siderite, green rusts, and magnetite (Fredrickson et al., 1998; Liu et al., 2001). In general, this type of concentrated batch reaction produced high enough concentrations of the products of biological Fe reduction to be detected using traditional techniques, such as lab-based XRD and Mossbauer spectroscopy. However, in order to investigate the transformation of Fe (hydr)oxide minerals under more natural conditions, Fendorf and coworkers (Hansel et al., 2003a, 2005; Kocar et al., 2006; Nico et al., 2009) transitioned to iron oxide coated sand, which was packed into columns. This allowed Fe biomineralization to be studied under conditions that transported microbial metabolites away from the reaction site. Although a variety of analytical methods were used to analyze the resultant Fe mineralogy, including SEM, HR-TEM, XRD, and Mossbauer spectroscopy, they found that the most accurate and quickest method that allowed the quantification of the various iron mineral phases was EXAFS spectroscopy combined with linear combination analysis (Hansel et al., 2003a, 2005). Using this technique, Hansel et al. (2005) demonstrated that the mineralogical transformation of Fe(III) (hydr) oxides is dependent on the Fe(III) flux resulting from microbial iron reduction. At high Fe(II) concentrations, the dominant mineralogical products include magnetite and goethite, whereas lepidocrocite and goethite are observed at lower Fe(II) concentrations. Interestingly, more reduced phases, such as green rusts and Fe(II)-bearing minerals, were not observed in any experiments where flow conditions were used. This research work has formed the basis for a series of studies that examine the effect of microbial iron reduction on the incorporation of other metals and metalloids, such as uranium and chromium, into iron oxide mineral structures during biological iron reduction and abiotic redox reactions (Ginder-Vogel and Sparks, 2010).

Widespread uranium contamination is present throughout the world as a result of natural uranium deposits, mining activities, and nuclear weapons and fuel production. Environmental uranium speciation is dominated by two oxidation states with markedly different properties. Uranium(VI), as the uranyl cation UO22+, is thermodynamically stable under oxidizing conditions and is highly soluble in the presence of dissolved bicarbonate. Although uranyl sorption to solids such as Fe (hydr)oxides may be appreciable, it is largely reversible and is thus subject to changes in aqueous conditions and Fe (hydr) oxide mineralogy. Dissolved uranium can be reduced through the transformation of U(VI) into U(IV), forming solid uraninite (UO₂), which is sparingly soluble under most environmental conditions. However, uraninite may be reoxidized, thereby releasing uranium, by many oxidants including O2, NO3, and Mn(IV) oxides and Fe(III) (hydr)oxides (Ginder-Vogel and Fendorf, 2008). Given the prevalence of Fe (hydr)oxide minerals in the environment and their critical role in controlling uranium mobility, much research has focused on the interaction of uranium complexes with iron, particularly as (hydr)oxide mineral phases. However, we have only recently begun to understand the role of iron (hydr)oxides in catalyzing uraninite oxidation and incorporation of uranium into the Fe (hydr)oxide mineral structure. Ginder-Vogel et al. (2006) and Ginder-Vogel and Fendorf (2008) used a combination of S-XRD and XAS to identify and quantify iron oxide minerals produced during the oxidation of biologically precipitated uraninite by ferrihydrite. This research revealed that ferrihydrite is capable of oxidizing biogenic uraninite; however, the oxidation reaction is ultimately limited by the conversion of ferrihydrite into more thermodynamically stable forms, such as lepidocrocite and goethite. Interestingly, during Fe(II) catalyzed ferrihydrite remineralization, U(VI) is substituted for between 3% and 6% of iron sites in transformation products (Nico et al., 2009). The substituted uranium is stable even in the presence of strongly complexing solutions (30 mM KHCO₃) and during redox cycling (Stewart et al., 2009) and can be environmentally important as a long-term uranium sink (Ginder-Vogel and Sparks, 2010).

Similar to uranium, chromium predominantly exists in the environment in two oxidation states, Cr(III) or Cr(VI). Chromium(VI), chromate, is highly toxic to humans and is quite soluble and hence mobile under most common environmental conditions. Conversely, Cr(III) is less toxic and generally immobile. There are many abiotic and biotic pathways of chromium reduction in the environment; however, under neutrophilic conditions kinetic considerations favor Cr(VI) reduction by either dissolved Fe(II) or Fe(II)-bearing mineral phases (Fendorf et al., 2002). The identification and quantification of chromium oxidation states, using XANES spectroscopy, is quite straightforward, due to a prominent preedge peak at 5993 eV, when Cr is present as Cr(VI) (Peterson et al., 1996, 1997), which is caused by a bound-state 1s to 3d transition. This transition is forbidden for centrosymmetric, octahedral Cr(II)O6 but is allowed for the noncentrosymmetric, tetrahedrally coordinated Cr(VI)O₄ molecule, due to mixing of the Cr(3d) and O(2p) orbitals. The intensity of this preedge feature can be used to quantify the proportion of Cr(VI) in a sample, at Cr(VI) concentrations greater than 1%-5%. Using this technique, several studies have examined Cr speciation in reducing Cr-contaminated soils (Fendorf and Zasoski, 1992; Patterson et al., 1997; Kendelewicz et al., 2000; Bank et al., 2007) and determined that less mobile Cr(III) was the dominant species in these systems; however, this may not always be the case in oxic systems. Using a combination of bulk XAS, μ-XRF and μ-XRD to analyze sediments from the arid, oxic, Cr-contaminated Hanford site in Eastern Washington state, in conjunction with flow-through column experiments, Ginder-Vogel et al. (2005) identified several Fe(II)-bearing phyllosilicate minerals as the primary sources of Cr(VI) reducing ability in these sediments. However, depending on geochemical conditions, as much as 50% of the solid-phase chromium remained in the hexavalent form.

In large part, the solubility of Cr(III) that is abiotically reduced by ferrous iron is determined in large part by the ratio of Cr(III) to Fe(III) in the (hydr)oxide precipitate of the general formula $Fe_XCr_{1-x}(OH)_3$ (Sass and Rai, 1987). The solubility of Cr(III)-hydroxide precipitates is proportional to the ratio of Cr(III) to Fe(III), with increased quantities of Fe(III) stabilizing the solid (Sass and Rai, 1987). Generally, the ratio of Cr to Fe in hydroxide solids is determined using extraction methods, which may be compromised by Fe contamination of ex situ environmental samples; however, EXAFS spectroscopy presents an alternative method for determining this molar ratio (Hansel et al., 2003b). The intensity of the corner-sharing peak at 3.48–3.56 Å, normalized to the first Cr–Cr(Fe) shell, has a linear relationship with the mole fraction of Cr(III) within a mixed Cr(III)–Fe(III) solid (Ginder-Vogel and Sparks, 2010).

1.3.5 Speciation of Metal(loids) in Soils

Some examples of studies that have used μ -XAS and μ -XRD to speciate metal(loids) in soils include those by Hunter and Bertsch (1998), Manceau et al. (2000), Isaure et al. (2002), Strawn et al. (2002), Ginder-Vogel et al. (2005), Nachtegaal et al. (2005), Roberts

et al. (2005), Arai et al. (2006), McNear et al. (2007), and Gräfe et al. (2008). A few examples of these studies are summarized below.

Nachtegaal et al. (2005) investigated the speciation of Zn in smelter-contaminated soils, employing $\mu\text{-XAS}$ and $\mu\text{-XRF}$, from a large site in Belgium in which part of the site had been remediated by adding beringite, an aluminosilicate material, compost, and planting metal tolerant plants. The other portion of the site was not treated. The objectives of the study were to determine how Zn speciation differed in the remediated (treated) and non-remediated (nontreated) soils. Specifically the study sought to determine if Zn-LDH phases were present in the soils and the stability of the zinc under different environmental conditions.

A large number of μ -XAS spectra for the treated (Figure 1.13b) and nontreated (Figure 1.13d) soils were collected at various regions of interest from the XRF spectra (Figure 1.13a, treated and Figure 1.13c, nontreated soils), as well as spectra for reference mineral, sorbed, and solution phases that were probable species in the soils. The μ -XAS spectra of the soils were analyzed via PCA. TT was then employed to determine spoil values for the known reference materials. The spoil value indicates how well the reference spectrum is matched to the principal components. The lower the spoil value, the better the match, and the more likely the reference material is contained in the soil sample. After the contributing standard phases are identified, LLSF is used to determine the amount (%) of each standard species within the individual sample spectrum making up the dataset. Additional details on µ-XAS applications and data analyses methods for heterogeneous systems can be found in Bertsch and Hunter (2001) and Manceau et al. (2000).

In the study of Nachtegaal et al. (2005), both mineral (e.g., willemite, hemimorphite, sphalerite) and sorbed (Zn-LDH) Zn species predominated in the treated and nontreated soils. The speciation differences in the treated and nontreated soils were slight, with the major difference being the presence of kerolite, a Zn phyllosilicate phase, found in the treated soil (Figure 1.13b). Significant quantities of Zn-LDH phases were formed in the nontreated soil (Figure 1.13d). Desorption studies, using both CaCl₂ and HNO₃ at pH 4 and 6, showed that the Zn in both remediated and nonremediated soils was quite stable, reflecting again the role that metal surface precipitates, that is, Zn-LDH phases, play in sequestering metals such that mobility and bioavailability are diminished.

Gräfe et al. (2008) used μ -XAS and μ -XRF to study the speciation of As in a copper-chromated-arsenate-contaminated soil to determine how co-contaminating metal cations (Cu, Zn, Cr) affected the speciation of As. Data analyses revealed that As occurred as a continuum of fully and poorly ordered copper-arsenate precipitates (63%–75% of As species) and surface adsorption complexes on goethite and gibbsite in the presence and absence of Zn. Other non-Cu-based precipitates such as scorodite, adamite, and ojuelaite were also found. These data point out that association of As with Cu suggests that the speciation of As in a contaminated soil is not entirely controlled by surface adsorption reactions but influenced significantly by the co-contaminating metal cation fraction.

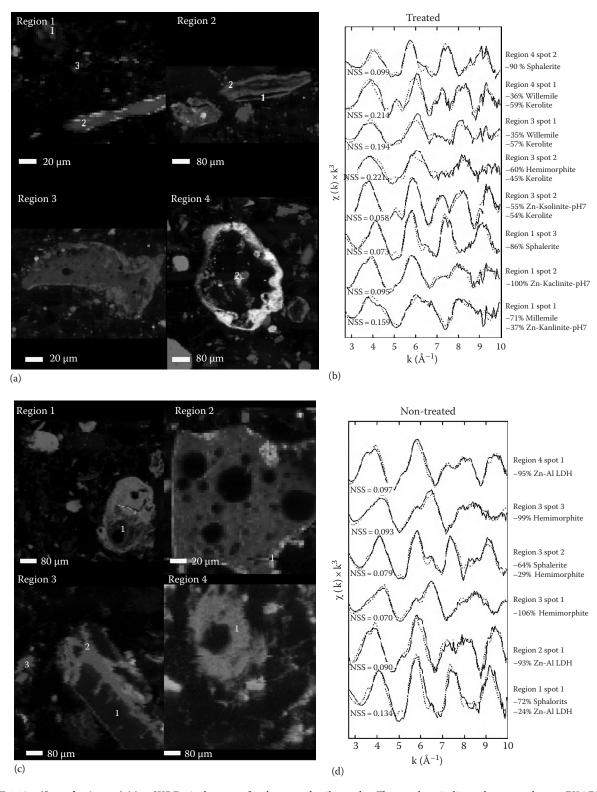

FIGURE 1.13 (See color insert.) (a) μ -SXRF tricolor maps for the treated soil samples. The numbers indicate the spots where μ -EXAFS spectra were collected. Red is indicative of the distribution of iron, green of copper, and blue of zinc. (b) μ -EXAFS spectra from selected spots on thin sections from the treated soil. (c) μ -SXRF tricolor maps for the nontreated soil samples. (d) μ -EXAFS spectra from selected spots on thin sections from the nontreated soil. The solid line indicates the raw $k^3c(k)$ data, and the dotted line indicates the best fits obtained with a linear fitting approach. (Reprinted from Nachtegaal, M., M.A. Marcus, J.E. Sonke et al. 2005. Effects of in situ remediation on the speciation and bioavailability of zinc in a smelter contaminated soil. Geochim. Cosmochim. Acta 69:4649–4664. Copyright 2005, with permission from Elsevier.)

1.3.6 Speciation of Nutrients in Soils and Biosolids

A number of studies have used XAS to speciate nutrients such as P in soils and biosolids (see references cited in Toor et al., 2006). Hesterberg et al. (1999) used XANES to investigate adsorbed and mineral phases of phosphate on Al- and Fe-oxides. They also showed that the predominant phase of phosphate in a North Carolina soil sample was dicalcium phosphate. Peak et al. (2002) investigated the speciation of P in alum-amended and nonamended poultry litter samples using XANES. Alum is used in the poultry industry to reduce the level of water-soluble P in poultry litter before it is land applied. First, phosphorus, sulfur, and calcium XANES were collected on the litter samples as well as spectra of reference materials that included aqueous and organic phosphates as well as Ca and Al phosphates and phosphate adsorbed on Al oxides. The experimental XANES spectra of the litter samples were then compared to the reference compounds via fingerprinting to determine the chemical species in the litter samples. In the unamended litter, the predominant P species were a mixture of aqueous phosphate, organic phosphate, and dicalcium phosphate. In the alumamended litter samples, the major species were P adsorbed on Al oxides, organic phosphate, and aqueous phosphate. These results would indicate that the addition of alum reduces the mobility of P in the litter material. There was no evidence of Al phosphate precipitates in the alum-amended samples. However, such phases could have occurred immediately after alum was added, as the pH is low, ca. 5, but then it increases with time to ca. 7. With the rise in pH, any initial Al phosphate precipitates would undergo dissolution. XANES, along with more detailed speciation analyses, including linear combination fitting, was used by Beauchemin et al. (2003), Toor et al. (2005), Shober et al. (2006), and Seiter et al. (2008) to more quantitatively speciate P in soils, turkey manures, and poultry litter. In order to get a better assessment of organic P species, which are known to be significant in poultry litter, Seiter et al. (2008) used PCA, TT, and LLSF to assess P speciation in alum-amended and nonamended poultry litter samples. They found that alum-amended poultry litter contained higher amounts of Al-bound P and phytic acid, whereas nonamended samples contained Ca-P minerals and organic P compounds.

1.3.7 Speciation of Metals in Hyperaccumulator Plants

Over the past few years, synchrotron-based XAS, XRF, XRD, and microtomography have been employed to enhance understanding of plant/soil interfacial processes and reactivity (Sarret et al., 2002, 2006; Küpper et al., 2004; Scheckel et al., 2004; McNear et al., 2005a, 2005b; Tappero et al., 2007). Of particular interest is determining the speciation and uptake mechanisms of metals into hyperaccumulator plants. Such an enhanced comprehension could prove invaluable in increasing the effectiveness of phytoremediation in decontaminating metal polluted

sites around the world. Phytoremediation is a "green" technology that uses plants to remove contaminants from the environment. Phytoextraction depends on unique plants, capable of accumulating higher than normal metal concentrations (e.g., >1000 ppm for Ni and Co and >10,000 ppm for Zn) (Baker, 1981; McNear et al., 2005a, 2005b). To better understand the mechanisms involved in metal hyperaccumulation and tolerance, it is imperative to know whether accumulated metals are bound by strong (specific) ligands or loosely associated with common organic acids (i.e., speciation) as well as where these metals are stored (i.e., localization or compartmentalization). The use of synchrotron-based methods to explore metal speciation and uptake mechanisms in plants is especially attractive because one can use "fresh" hyperaccumulator plant tissues (in vivo) with micrometer resolution and investigate distribution and association of the metals in the plant tissue on two-dimensional (µ-XRF) and three-dimensional (microtomography) scales and determine direct metal speciation (µ-XAS). Several studies have employed these techniques to elucidate Ni and Co speciation in Alyssum murale, an important Ni hyperaccumulator plant from the Brassicaceae family that is native to serpentine soils throughout Mediterranean southern Europe (McNear et al., 2005a, 2005b; Tappero et al., 2007).

Tappero et al. (2007) studied metal localization and elemental associations in A. murale plants exposed to metal (Ni, Zn, and Co) co-contaminants using synchrotron-based μ-XRF, μ-XAS, and computed microtomography. Two-dimensional XRF images of A. murale leaves showed a marked localization pattern for Co compared with Ni and Zn. The Ni distribution was predominately uniform (Figure 1.14), which is consistent with previous findings that Ni is compartmentalized in epidermal tissues, that is, vacuolar sequestration (Kramer et al., 1997; Krämer et al., 2000; Broadhurst et al., 2004a, 2004b). Zinc distribution was similar to Ni and was not hyperaccumulated. Cobalt, however, was preferentially localized at the tips and margins of A. murale leaves as precipitate phases (Figure 1.14). Differential absorption computed microtomography images (Figure 1.15) of a hydrated A. murale shows leaf Co enrichment in apoplast tissue. Cobalt near leaf tips was localized primarily on the leaf exterior, and the hyperaccumulation mechanism was via exocellular sequestration (Tappero et al., 2007).

1.4 Future Needs

As our knowledge of environmental systems continues to advance, it is critical that synchrotron-based techniques continue advancing with the field. Currently, a primary limitation of the application of these techniques to environmental systems is the availability of adequate amounts of beamtime. This problem can begin to be resolved by advances in both user support and instrumentation. Several improvements in user administration and services, including standardized data collection software, state-of-the-art data analysis software, increased beamline support staff, and improvements in laboratory support facilities, would allow for the more efficient use of limited

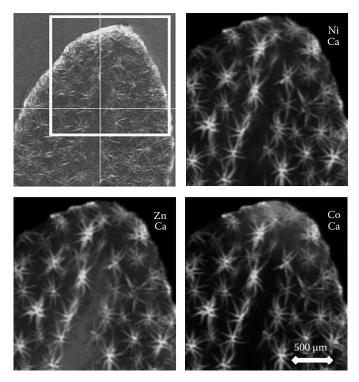

FIGURE 1.14 (See color insert.) Synchrotron x-ray microfluorescence (μ-SXRF) images of the nickel (Ni), cobalt (Co), and zinc (Zn) distributions in a hydrated *A. murale* leaf from the Ni + Co + Zn treatment. Leaf trichomes are depicted in the Ca channel. The camera image shows the leaf region selected for SXRF imaging. (Reprinted from Tappero, R., E. Peltier, M. Grafe et al. 2007. Hyperaccumulator *Alyssum murale* relies on a different metal storage mechanism for cobalt than for nickel. New Phytol. 175:641–654. With permission from Wiley-Blackwell.)

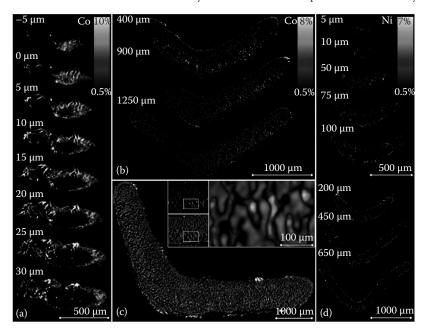

FIGURE 1.15 (See color insert.) Differential absorption (DA-CMT) tomographic projections (5.1 μm slices) of hydrated *A. murale* leaves depicting (a) cobalt (Co) distribution in the leaf-tip region, (b) Co distribution in the bulk-leaf region, (c) Co distribution in relation to the leaf cell structure (gray), and (d) nickel (Ni) distribution in the leaf-tip and bulk-leaf regions. Leaves were collected from a Co-treated plant (a–c) and from a Ni-treated plant (d). Sinograms recorded above and below the Co or Ni K-edge energy (+30 and −100 eV, respectively) were computationally reconstructed, and the resulting projections were subtracted (above – below) to reveal the metal distribution in leaves. Distances are relative to the leaf tissue at the tip as determined from leaf structure images (i.e., below-edge projections). (Reprinted from Tappero, R., E. Peltier, M. Grafe et al. 2007. Hyperaccumulator *Alyssum murale* relies on a different metal storage mechanism for cobalt than for nickel. New Phytol. 175:641–654. With permission from Wiley-Blackwell.)

beamtime. The heterogeneity of environmental samples requires both the application of a wide array of techniques, including x-ray spectroscopic and traditional ones, and more time using each individual technique. The enhanced intensity and flux of third-generation synchrotron light sources allow for the analysis of both lower concentration elements and smaller samples; however, many environmental samples also require a broad energy range (5-50 keV), high energy resolution (0.1 eV), and a range of spatial resolutions (bulk, micro, and nano). Additionally, unique endstation capabilities, including flow-through reaction cells and anaerobic gloveboxes, coupled with fast-scanning, high energy resolution fluorescent detection and simultaneous collection of XRD and XAS data, will take advantage of the unique ability of x-ray absorption to analyze samples in situ, allowing a new generation of complex environmental problems to be solved (Ginder-Vogel and Sparks, 2010).

2.1 Introduction

Soil may be regarded as a complex bioorganomineral system where minerals, water, air, organic matter (OM) (humus), and microorganisms interact at scales ranging from nanometers to kilometers. Figure 2.1 gives a simplified diagram of the clay-humus-microbe in soil. In this chapter, we focus attention on the interactions of clays with OM, a process that is arguably as important to sustaining life on earth as is photosynthesis (Jacks, 1973). The clay-organic interaction plays a key role in stabilizing soil OM against microbial decomposition, thus making soils suitable for plant growth, while photosynthesis produces biomass for inputs into soil, as well as for human and animal consumption.

It has long been recognized that much of the OM in soil is closely associated with the clay fraction (Schloesing, 1874). The chemistry of clay-organic reactions, however, is a relatively young discipline, dating back to the early 1940s. The publication of Greenland's papers (1965a, 1965b) provided the stimulus for a systematic investigation into the behavior of well-defined small and polymeric organic molecules at specific clay mineral surfaces. The advances in this branch of clay-organic chemistry that have since been made can be traced in the reviews and monographs by Mortland (1970), Theng (1974, 1979, 1982), Theng and Tate (1989), Hayes and Mingelgrin (1991), Clapp et al. (1991), Oades (1989), Violante and Gianfreda (2000), Yariv and Cross (2002), and Lagaly et al. (2006).

Progress in understanding the clay-organic interaction in soil environments has been hampered by the diversity and structural complexity of the reactants, the variety of bonding modes that operate simultaneously, and the microbial participation (Theng, 1980; Huang and Schnitzer, 1986; Oades, 1988; Huang, 2004; Kögel-Knabner et al., 2008). In response, the International Society of Soil Science established Working Group MO in 1990, which became

Commission 2.5 (Soil Physical/Chemical/Biological Interfacial Reactions) of the International Union of Soil Sciences in 2004. Working Group MO and Commission 2.5 have since sponsored five international symposia on soil mineral–microbe–organic interactions (ISMOM), the latest one being held in Pucón, Chile, in 2008 (ISMOM, 2008). The titles of the books arising from these symposia—Environmental Impact of Soil Component Interactions (Huang et al., 1995), Effect of Mineral–Organic–Microorganism Interactions on Soil and Freshwater Environments (Berthelin et al., 1999), Soil Mineral–Organic Matter–Microorganism Interactions and Ecosystem Health (Violante et al., 2002), and Soil Mineral–Microbe–Organic Interactions: Theories and Applications (Huang et al., 2008)—reflect the issues, concerns, and developments in this field of soil research.

Even after nearly five decades of investigation, some details about the clay-organic interaction await clarification. This is because progress in soil mineralogy, soil OM chemistry, and soil ecology has been slow and incremental, while soil research over the last two decades has focused more on "environmental" issues than basic aspects. The clay-organic interaction has recently attracted renewed interest, however, because of its important role in stabilizing and sequestering organic carbon (OC) in soil (Kaiser and Guggenberger, 2000, 2003; Swift, 2001; Kleber et al., 2005; Chenu and Plante, 2006; Basile-Doelsch et al., 2007; Huang, 2008). This relationship was integral to the development and refinement of models describing the dynamics of carbon in soil and their impact on greenhouse gas emissions (Jastrow and Miller, 1997; Smith et al., 1997; Liski et al., 1999; Jenkinson and Coleman, 2008).

Besides being a principal determinant in the stabilization of OC in soil, the clay-organic interaction is involved in essential ecological services and functions, ranging from regulating water storage and nutrient cycling, through adsorbing and

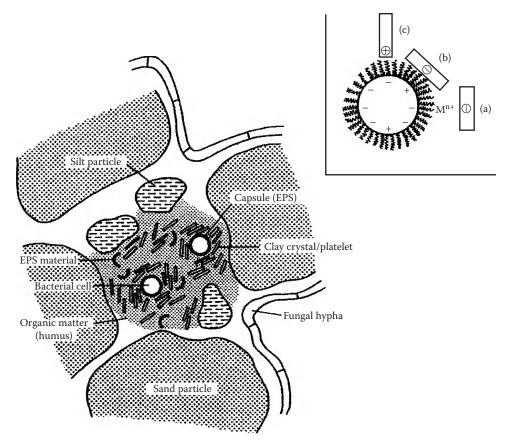

FIGURE 2.1 Diagram showing the association of minerals, OM, and microbes in soil. Bacterial cells with a coat of extracellular polysaccharides (EPS) are enveloped by clay particles. Inset shows an enlarged view of a bacterial cell with its compliment of EPS. Under normal pH conditions, the cell has a net negative charge. Most clay particles adhere to the cell surface by bridging through polyvalent cations, Mⁿ⁺ (a) although some may be attached directly by electrostatic interactions, indicated by (b) and (c). (Reprinted from Theng, B.K.G., and V.A. Orchard. 1995. Interactions of clays with microorganisms and bacterial survival in soil: A physicochemical perspective, p. 123–143. *In* P.M. Huang, J. Berthelin, J.-M. Bollag, W.B. McGill, and A.L. Page (eds.) Environmental impact of soil component interactions. Vol. II. CRC Lewis Publishers, Boca Raton, FL. With permission from Taylor & Francis.)

transporting metal and organic contaminants, to serving as a source or sink of OC and greenhouse gases. Improved understanding of the clay-organic interaction in this context is therefore a key to using soils for food, fiber, and fuel production in a sustainable manner. This chapter describes the interactions of clay-size minerals in soil (phyllosilicates, short-range order minerals, and metal (hydr)oxides) with natural OM and the effects of these interactions on some soil properties and functions.

2.2 Structures, Properties, and Reactivity of Soil Clays and Organic Matter

2.2.1 Clay-Size Minerals in Soil

Being the "living skin of earth," soil contains a wide variety of minerals and organic substances as well as a myriad of microorganisms. Here we focus on the clay fraction, which comprises particles of $<2\mu m$ equivalent spherical diameter, including nanoparticles ($<100\, nm$). The clay-size minerals in soil are very reactive not only because of their large surface area, but more so

because a high proportion of the structural atoms are exposed on surface sites where chemical bonds are broken and coordination requirements are unsatisfied. The excess energy associated with such surface defects and dislocations lies behind their propensity to interact with water, plant nutrients, metals, and organic substances (Oades, 1988, 1989; Hochella et al., 2008; Theng and Yuan, 2008). By the same token, clay particles are tiny because they have a high density of structural defects, as a result of which nucleation is favored over crystal growth (Meunier, 2006).

The clay fraction of soils consists of various phyllosilicates (clay minerals), short-range order minerals, metal (hydr)oxides, and associated humic substances (HS). The clay fraction may also contain quartz and feldspar. The structures and properties of some common clay-size ("fine-grained") minerals are outlined below. Chapters 20 through 23 of *Handbook of Soil Sciences: Properties and Processes* and the books edited by Dixon and Weed (1989) and Bergaya et al. (2006) should be consulted for more details.

2.2.1.1 Phyllosilicates

The basic structural unit of phyllosilicates (layer silicates) is a layer formed by combining a silica tetrahedral sheet and an alumina octahedral sheet in a given proportion. In 1:1 type phyllosilicates, such as kaolinite, each layer is made up of one tetrahedral and one octahedral sheet, giving a thickness (basal spacing) of about 0.7 nm (Figure 2.2, top). Another species in this group of layer silicates is halloysite whose structure is similar to that of kaolinite but the 1:1 layers are separated by a sheet of water molecules. As a result, the basal spacing of halloysite is 1 nm, which decreases to 0.7 nm on dehydration (Joussein et al., 2005; Brigatti et al., 2006). On the other hand, individual layers

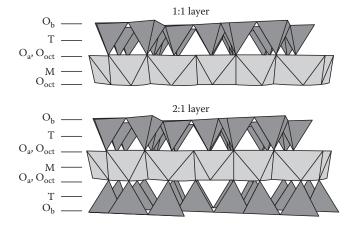

FIGURE 2.2 Models of a 1:1 and 2:1 layer structure. O_a , O_b , and O_{oct} refer to tetrahedral apical, tetrahedral basal, and octahedral anionic position, respectively. M and T indicate the octahedral and tetrahedral cation, respectively. The thickness of a 1:1 layer is about 0.7 nm, while that of a 2:1 layer is about 1 nm. (Reprinted from Brigatti, M.F., E. Galan, and B.K.G. Theng. 2006. Structures and mineralogy of clay minerals, p. 19–86. *In* F. Bergaya, B.K.G. Theng, and G. Lagaly (eds.) Handbook of clay science. Elsevier, Amsterdam, the Netherlands. With permission.)

in 2:1 type phyllosilcates consist of an octahedral sheet sand-wiched between two tetrahedral sheets (Figure 2.2, bottom), giving a layer thickness of about 1 nm. Since the interlayer space may contain inorganic cations with or without water (e.g., smectite, mica), or metal hydroxides (e.g., chlorite), the basal spacing of 2:1 phyllosilicates commonly exceeds 1 nm. Phyllosilicates in soil often occur as mixed-layer or interstratified minerals, such as mica–smectite, mica–chlorite, and kaolinite–smectite rather than as single mineral species (Schulze, 1989).

As a result of isomorphous substitution (e.g., Al3+ for Si4+ in the tetrahedral sheet and Mg2+ for Al3+ in the octahedral sheet) within the layers, many clay minerals have a permanent negative charge, which is balanced by inorganic cations (e.g., Na+, Ca2+) occupying interlayer sites. Since these chargebalancing cations ("counterions") are exchangeable, many phyllosilicates have a permanent cation exchange capacity (CEC) that does not vary with the pH of the ambient solution. Thus, the high CEC values (90–130 cmol, kg⁻¹) of smectites is a reflection of extensive isomorphous substitution. By comparison, the CEC of kaolinite rarely exceeds 10 cmol, kg⁻¹ because of limited substitution in layer structure, and its CEC can vary with solution pH. Some nanoclays in soil (e.g., allophane) have little, if any, isomorphous substitution. Both the surface charge and CEC of such materials are therefore controlled by solution pH (Table 2.1).

2.2.1.2 Short-Range Order Minerals

Imogolite and allophane are short-range order or poorly crystalline nanosize aluminosilicates although imogolite has long-range order along the tubule axis (Wada, 1989; Farmer and Russell, 1990). The unit particle of imogolite is a slender hollow tubule with an outer diameter of about 2 nm. The tubule wall

TABLE 2.1 Composition, Charge Characteristics, and Specific Surface Area of Common Soil Minerals

Minerals	Formula	CEC (cmol _c kg ⁻¹)	PZC	Specific Area (m² g ⁻¹)
Kaolinite	Si ₂ Al ₂ O ₅ (OH) ₄	3–15	4-5	5–30
Halloysite (7 Å)	$Si_2Al_2O_5(OH)_4$	40-50		5-10
Halloysite (10 Å)	$Si_2Al_2O_5(OH)_4 \cdot 2H_2O$			10-40
Montmorillonite	$M_{0.33}Si_4(Al_{1.67}Mg_{0.33})O_{10}(OH)_2$	80-150		800 (CPB)
Quartz	SiO ₂	0.6-5.3	2-3	1-3.6
Goethite	α-FeOOH	0-6	7-8	14-177
Hematite	α -Fe ₂ O ₃	0-6	8-8.5	30-50
Gibbsite	γ -Al(OH) ₃	0.2-3	8-9	~50
Imogolite (natural)	$(OH)_3Al_2O_3SiOH$ (Al/Si = 2.0)	Variable pH-dependent	6.8	822-1031 (EGME)
Allophane (synthetic)	Al/Si = 1.15-1.74	Variable pH-dependent	5.5-6.9	638-897 (EG, EGME)
Ferrihydrite (6-line)	$\text{Fe}_{1.55}\text{O}_{1.66}(\text{OH})_{1.34}$	Variable pH-dependent	5.3-7.5	$200-500^{b}$
Birnessite (synthetic) ^a	δ -MnO $_2$	Variable pH-dependent	2.7	72 (EGME)

consists of an outer curved Al octahedral (gibbsitic) sheet to which O₃SiOH groups are attached on the inside (Cradwick et al., 1972; Farmer and Fraser, 1979). The unit formula of imogolite is usually written as (OH)₃Al₂O₃SiOH, showing an Al/Si ratio of 2.0, and indicating the sequence of ions from the periphery to the center of the tubule where the orthosilicate group shares three oxygens with aluminum. Unlike imogolite, allophane has no fixed chemical composition in that its Al/Si ratio can vary between 1 and 2. Irrespective of composition and origin, however, the unit particle of allophane is a hollow spherule with an outer diameter of 3.5–5.0 nm. The 0.7–1.0 nm thick spherule wall is composed of an outer gibbsitic sheet and an inner Si sheet. Defects in the wall structure give rise to perforations of ~0.3 nm in diameter (Wada, 1989; Parfitt, 1990; Brigatti et al., 2006).

Consisting of nanosize spherules, allophane has a large specific surface area (SSA). A value of about $1000\,\mathrm{m^2~g^{-1}}$ is calculated for the external (interspherule) and internal (intraspherule) area on the basis of unit particle size and density, while $700-900\,\mathrm{m^2~g^{-1}}$ is measured by retention of ethylene glycol and ethylene glycol monoethyl ether (Hall et al., 1985; Wada, 1989; Table 2.1). Allophane has a variable (pH-dependent) surface charge attributable to the protonation and deprotonation of (OH)Al(H₂O) groups exposed at perforations along the spherule wall. The point of zero net charge of allophanes ranges from pH 5 to 6 (Theng et al., 1982; Clark and McBride, 1984; Mora et al., 1994; Hashizume and Theng, 2007). The chemical properties of allophane-rich soils reflect the surface charge characteristic of this nanoclay.

Although allophane, imogolite, and halloysite occur in nonvolcanic soils, such as the lower horizons of podzols (Farmer and Russell, 1990), they are especially widespread in volcanic soils (Dahlgren et al., 2004). In humid environments, these minerals form by rapid weathering of volcanic ash ("tephra") where nucleation and precipitation are kinetically favored over crystal growth. Another common nanosize mineral in volcanic soils is ferrihydrite. Like allophane and imogolite, ferrihydrite is a "natural" (soil) nanomineral without microscale analogues. Thus, the size of ferrihydrite particles has never been observed to exceed 20 nm in diameter but is more typically \leq 10 nm (Hochella, 2008). The formation and persistence of allophane, imogolite, and ferrihydrite in soil are greatly influenced by OM. Eusterhues et al. (2008), for example, show that even small amounts of waterextractable OM can appreciably reduce the particle size and structural order of ferrihydrite, while the input of large amounts of plant biomass tends to inhibit allophane and imogolite formation (Inoue and Huang, 1986, 1990; Parfitt, 2009).

2.2.1.3 Metal (Hydr)oxides

Most soils also contain a variety of metal "(hydr)oxides" (an umbrella term for oxides, hydroxides, and oxyhydroxides), among which those of Al, Fe, and Mn are very common. Like allophane, Al-, Fe-, and Mn-(hydr)oxides are short-range order, nanosize minerals capable of interacting with OM. These minerals often occur as a "coat" over clay mineral surfaces (Theng and Yuan, 2008), and affect soil properties. Soil color, for example, reflects the presence of Fe (hydr)oxides since these nanosize minerals are

strongly colored: hematite (α-Fe₂O₃, red), maghemite (γ-Fe₂O₃, reddish-brown), magnetite (Fe₃O₄, black), goethite (α-FeOOH, yellow-brown), lepidocrocite (γ-FeOOH, orange), and ferrihydrite $(Fe_{1.5}O_{1.66}(OH)_{1.34}$, red brown). In general, however, the color of surface soils is related to the OC content (Konen et al., 2003). Further, ferrihydrite can transform into hematite through a solidstate reaction, or into goethite by dissolution and precipitation (Schwertmann, 2008). The formation of Al-(hydr)oxides in soil commonly involves the release of Al from primary aluminosilicates, followed by its hydrolysis and precipitation. In terms of soil occurrence, gibbsite [γ-Al(OH)₃] is more common than boehmite [AlO(OH)]. Like their iron counterparts, the (hydr)oxides of Mn (III), Mn (IV), and Mn (III, IV) in soil form by the oxidation of Mn (II), released through weathering of Mn-containing rocks. The oxidation process may be chemically controlled or mediated by bacteria and fungi. The most common species of Mn-(hydr) oxides in soil are birnessite and vernadite. The surface charge of metal-(hydr)oxides is an important factor affecting their interactions with OM in soil. The point of zero charge of most soil Mn-(hydr)oxides is less than pH 4, while that of their aluminum and iron counterparts is larger than pH 7 (Table 2.1). Thus, in the pH range (4.5-7.5) of most soils, Mn-(hydr)oxides are negatively charged whereas the surface charge of Al- and Fe-(hydr)oxides is positive (Theng and Yuan, 2008).

2.2.2 Organic Matter

A large part of the OC on the earth surface, including the atmosphere, pedosphere, biosphere, and hydrosphere, is to be found in soil. Globally, the top 1 m of soil contains about 1500 Pg (1 Pg = 10¹⁵g) of carbon, that is, about 2.5 times as much carbon as in the terrestrial vegetation (≈600 Pg), and about twice as much as in the atmosphere (≈750 Pg) (Batjes, 1996; Almendros, 2008). About 60% of the nonliving ("dead") OM in soil occurs in the form of HS. The other 40% consists of particulate OM (i.e., organic fragments with a recognizable cellular structure), dissolved OM (e.g., amino acids, sugars, organic acids, phenolic compounds), and non-humic biopolymers (e.g., enzymes, proteins, polysaccharides, lipids, nucleic acids) (Baldock and Nelson, 2000; Baldock and Nelson, Chapter 11 of Handbook of Soil Sciences: Properties and Processes). The content of OM in soil is not directly measurable but may be estimated by multiplying the OC content (obtained by either dry combustion or wet digestion) by 1.724, that is, $\%OM = 1.724 \times \%OC$.

It is not our intention to summarize the large volume of literature on the separation, characterization, and physicochemical properties of the various components of soil OM (Schnitzer and Khan, 1972, 1978; Flaig et al., 1975; Aiken et al., 1985; Stevenson, 1994; Baldock and Nelson, 2000; Baldock and Nelson, Chapter 11 of *Handbook of Soil Sciences: Properties and Processes*). Rather, the emphasis is on the interactions of OM with clay-size minerals and their impact on soil properties and environmental changes. Further, we exclude plant litter, macroorganic matter (>250 μm in size), charcoal, and the "light fraction" (obtainable by flotation on liquids with densities of 1.6–2.0 Mg m $^{-3}$) from the discussion, but include HS and the microbial biomass.

HS are the most important class of organic materials in the soil environment in terms of quantity, stability, and ubiquity. They are conventionally divided into three fractions based on their solubility in alkali or acid: humic acid (alkali-soluble), fulvic acid (alkali- and acid-soluble), and humin (alkali- and acid-insoluble). Although these definitions are operational rather than chemical, humin represents the fraction that is so strongly bound to clay-size minerals as to resist extraction by alkali and acid. The humin fraction accounts for up to 50% of the total OM in soil, and its radiocarbon (¹⁴C) age often exceeds 1000 years (Horwath, 2008).

The microbial biomass accounts for less than 5% of the OC in soil. Nevertheless, microorganisms play a determining role in the turnover and cycling of nutrients as well as in aggregate formation and stabilization (Figure 2.1). The microbial biomass may be estimated by several methods, including chloroform fumigation-incubation/extraction and determination of adenosine triphosphate (Jenkinson and Powlson, 1976; Vance et al., 1987; Oades, 1989).

A long-held view is that HS are a mixture of linear polymers of high molecular weight (>10,000 Da), formed by heteropolycondensation of various biological precursors, such as phenolic acids, peptides, oligosaccharides, and fatty acids, held together by covalent and hydrogen bonding (Kononova, 1966; Flaig et al., 1975; Stevenson, 1994). In basic or low ionic strength solutions, these polymers adopt a random-coil conformation. The coils become denser, more rigid, and more compact in acidic or high ionic strength solutions (Oades, 1989; Swift, 1999). The macromolecular random-coil concept, however, is being displaced by one in which HS consist of aggregates of biologically derived molecules of relatively low molecular weight (200-3000 Da). The various molecules in the supramolecular structure or self-associating aggregate are bound by weak dispersive and hydrophobic interactions, forming micelles in solution in which interior hydrophobic regions are separated from the aqueous surrounding by exterior hydrophilic portions (Piccolo, 2001; Sutton and Sposito, 2005).

We should point out, however, that many low-molecular-weight biomolecules in soil, such as amino acids, sugars, and polyphenols can undergo polymerization and/or polycondensation. Being catalyzed by enzymes and minerals, these processes give rise to the browning reaction and the dark color of HS (Stevenson, 1994; Huang, 2000; Gonzalez and Laird, 2004). Moreover, most biomolecules are crystalline whereas HS are essentially amorphous. Nevertheless, biomolecules may be attached to, or encapsulated by, humic polymers. Thus, HS are not merely aggregates of biologically derived molecules but comprise polymeric materials into which various biomolecules are "trapped" and preserved (Schulten and Schnitzer, 1995; Huang and Hardie, 2009).

2.3 Clay-Organic Interactions

The ability of clays and clay minerals to take up organic substances has been known since antiquity. An example is the use of water slurries of calcium montmorillonite for cleaning raw wool (by removing grease and dirt) that dates back to 5000 BC. This process, known as fulling, gave rise to the term "fuller's earth" (Robertson, 1986). In his *Natural History*, Pliny the Elder (23–79 AD) described the use of clays for curing gastrointestinal ailments. The therapeutic activity of clays is based on their propensity for adsorbing organic toxins and bacteria (Carretero et al., 2006).

2.3.1 Mechanisms of Clay-Organic Interactions

As already remarked, clay-size minerals in soil are very reactive toward external molecules because of their tiny particle size, large surface area, high density of structural defects, and peculiar charge characteristics. We should also add that these minerals seldom exist as discrete, "clean" particles in soil; rather, they are associated with soil OM (humus), including microorganisms (Figure 2.1).

Because of the complexity, diversity, and heterogeneity of clay-size soil minerals and soil OM, the clay-organic interaction has largely been investigated by reacting specific phyllosilicates with well-defined small organic compounds and biomolecules (Mortland, 1970; Theng, 1974; Oades, 1989; Hayes and Mingelgrin, 1991; Yariv and Cross, 2002; Lagaly et al., 2006). The principles and underlying mechanisms that emerge from these studies have been extended to the sorption of organic polymers and HS (Theng, 1979; Clapp et al., 1991; Essington, 2003; Sposito, 2008). Among the phyllosilicates, montmorillonite has been the single, most widely used species because of its large surface area (700–800 m² g⁻¹), CEC (~100 cmol_c kg⁻¹), and propensity for intercalating a wide variety of organic molecules.

2.3.1.1 Interactions with Low-Molecular-Weight Organic Compounds

Nonionic, polar organic molecules must compete with water for the same sites around the exchangeable cation if adsorption is to occur. Thus, little adsorption takes place from dilute aqueous solutions for molecules with less than five carbon atoms (Hoffmann and Brindley, 1960). In order to minimize competition from excess water, the organic solute is often added at a high concentration, in an organic solvent, or as a liquid, vapor, or solid to dry montmorillonite. In conjunction with x-ray diffractometry, infrared spectroscopy has provided strong evidence to show that the intercalated organic is associated with the exchangeable cation through ion-dipole interactions (Mortland, 1970; Theng, 1974). For montmorillonite containing counterions of low hydration energy (e.g., Na+), the polar group of the organic molecule can associate directly with the cation. This mode of interaction may be regarded as one of ligand exchange for the cation-coordinated water molecules as a result of which the interlayer contracts and the basal spacing decreases. With counterions of high hydration energy (e.g., Ca2+, Mg2+), on the other hand, the organic molecule tends to interact through a water bridge, that is, by hydrogen bonding between its polar group and water in the primary hydration shell of the exchangeable cation. The intercalated organic species (e.g., maleic hydrazide) may simultaneously associate with the interlayer siloxane surface through hydrogen bonding (Cornejo and Hermosin, 1996).

Being essentially hydrophobic, the siloxane surface can also sorb nonionic organic molecules through hydrophobic interactions as Laird et al. (1992) have proposed for atrazine. Further, the entropy change involved in moving fully hydrated atrazine from water to a partially hydrated interlayer space contributes to sorption affinity (Chappell et al., 2005). Sorption is also enhanced when organic intercalation or high solution ionic strength induces the dehydration and collapse of the interlayer space (Li et al., 2006, 2007). Thus, the combination of ion-dipole and hydrophobic interactions with interlayer collapse (by dehydration) enables some smectites to sorb many nonionic organics even from aqueous suspensions. Low-charge smectites containing cations of low hydration energy would have extensive siloxane "patches" between exchangeable cations available for sorption relative to their high-charged counterparts. De Oliveira et al. (2005), for example, found that more carbaryl was sorbed by low- than by high-charged smectites, and sorption decreases in the order Ca > K > Na. Similar results were obtained with p-nitrocyanobenzene (Charles et al., 2006). Molecules containing aromatic π -systems can interact with mineral surfaces (and HS) through the formation of "electron donor-acceptor" complexes, including cation- π and n- π interactions. As the name suggests, the former refers to the interaction between cations and the planar surface of aromatic π -electron donors, while the latter denotes the interaction between the oxygens of the siloxane surface (electron donors) and the ring structures (electron acceptors) of substituted aromatic compounds, notably nitroaromatics (Weissmahr et al., 1996; Keiluweit and Kleber 2009). That some organic compounds (e.g., benzidine, benzene) can donate electrons to the clay surface or interlayer transition metal cations, giving rise to deeply colored complexes, has long been recognized (Doner and Mortland, 1969; Theng, 1971).

Positively charged organic molecules, notably alkylammonium ions, intercalate into montmorillonite by cation exchange, that is, by replacing the inorganic counterions from the interlayer space. Although cation exchange is the principal mechanism involved, van der Waals and hydrophobic interactions between the alkyl chain and the interlayer surface, and entropy effects contribute to the adsorption energy (Theng et al., 1967; Vansant and Uytterhoeven, 1972). With long-chain quaternary ammonium ions, adsorption may exceed the CEC. These ions may intercalate as a monolayer, a bilayer, a pseudotrilayer, or a paraffin-type structure depending on the alkyl chain length, the layer charge density of the clay mineral, and the organic loading (Lagaly et al., 2006).

Organically modified montmorillonites or organoclays have long been used as thickening agents in ink, lubricants, ointments, and paints (Jordan, 1949, 1963). More recently, organoclays have been used for pollution control and the production of claypolymer nanocomposites (Beall, 2003; Churchman et al., 2006; Theng et al., 2008; Calabi Floody et al., 2009). Because of their superior mechanical, thermal, gas-barrier, and fire-retardant

properties, these composite materials have found applications in a wide range of industries, from automobiles and electronics to sports gear and food packaging. A discussion of clay–polymer nanocomposites lies beyond the scope of this chapter. For details about the synthesis, properties, and uses of clay-based composite materials, we refer to the reviews by Alexandre and Dubois (2000), Ray and Okamoto (2003), Zheng et al. (2005), Ruiz-Hitzky and Van Meerbeek (2006), and Chen et al. (2008).

Little, if any, adsorption occurs with negatively charged organic compounds because they tend to be repelled by the negatively charged clay mineral surface. Nevertheless, appreciable uptake can take place in the presence of polyvalent counterions acting as a bridge between the anionic groups of the organic species and the silicate surface. This mode of interaction is therefore referred to as cation bridging. Under acid conditions (pH < 5), the edge surface of clay minerals would become positively charged through protonation of hydroxyl groups coordinated to aluminum and hence can adsorb anionic organic compounds by electrostatic interactions (anion exchange). A more important mode of bonding, however, is ligand exchange between the anionic group of organic species and surface hydroxyl groups of clay minerals and metal (hydr)oxides. The affinity of allophane for 5'-adenosine monophosphate (5'-AMP), for example, is much greater than for either adenine or adenosine. This may be ascribed to ligand exchange between the phosphate of 5'-AMP and the hydroxyl of (OH)Al(H2O) groups, exposed at surface defect sites (Hashizume and Theng, 2007). As described below, ligand exchange is a major mode of interaction between soil clays and HS.

The principles outlined above would equally apply to the interactions of nonionic pesticides (examples of which have already been given), organic pollutants, and bioorganic compounds with clay mineral surfaces. As would be expected, the sorption of variable-charged biomolecules (e.g., amino acids, purines, nucleosides) is sensitive to medium pH since the charge characteristics of both solute and mineral surface are pH-dependent (Theng, 1974; Hashizume and Theng, 1999, 2007).

2.3.1.2 Interactions with Humic Substances

Whether they exist as macromolecules, adopting randomcoil conformations, or as supramolecular structures, forming micelles, HS in solution would behave as polyanions. As such, HS would be repelled by negatively charged clay particles. In the presence of polyvalent cations, however, appreciable adsorption can occur, through cation bridging (inner-sphere bridging complexation), or water bridging (outer-sphere bridging complexation) (Theng, 1976; Theng and Scharpenseel, 1976; Theng and Tate, 1989; Varadachari et al., 1991; Sposito, 2008). In acidic soils, anion exchange involving the positively charged edge surface of clay particles would make an appreciable contribution, while in soils with a high base status, cation bridging (through Ca²⁺) would be prevalent. Anion exchange is especially important with Al- and Fe-(hydr)oxides since their surfaces are positively charged in the pH range of most soils. Ligand exchange between the carboxylate groups of HS and hydroxyls (or water molecules) coordinated to metal ions exposed on clay particle edges and at the surface of metal (hydr)oxides can occur over a wide range of pH values. Besides being characterized by the release of OH⁻ (or H₂O) into solution (see Equation 2.1), ligand exchange shows a high degree of anion specificity, slow or little desorption, and a shift of the surface charge to more negative values (McBride, 1994). Other (secondary and indirect) modes of interactions include hydrogen bonding, van der Waals, and entropy effects (Table 2.2). Because of the diversity of minerals and HS in soil, and variations in environmental conditions, several bonding modes may operate simultaneously, while the relative importance of each mechanism would change from soil to soil (Jardine et al., 1989; Kögel-Knabner et al., 2008).

Ligand exchange is the dominant mechanism underlying the adsorption of HS by allophane, imogolite, and iron (hydr)oxides because these nanosize minerals have a large concentration of

surface hydroxyl groups (Parfitt et al., 1977; Mott, 1981; Gu et al., 1994; Kaiser et al., 1997; Yuan et al., 2000; Farmer and Lumsdon, 2001). Equation 2.1 illustrates the situation for allophane where numerous (OH)Al($\rm H_2O$) groups are exposed at defect sites (perforations) along the spherule wall (Theng et al., 1982; Hashizume and Theng, 2007):

[allophane
$$-Al(H_2O)(OH)]^0 + [R.COO]^{n-}$$

 \rightarrow [allophane $-Al(H_2O)(COO.R)]^{(n-1)^-} + OH^-$ (2.1)

where $[R.COO]^{n-}$ denotes a humic molecule containing n carboxylate functional groups.

Thus, volcanic ash soils can accumulate and stabilize OM through interactions with allophane, imogolite, and ferrihydrite together with the formation of Al-humus complexes.

TABLE 2.2 Possible Mechanisms of Bonding between Humic Substances and Clay Mineral Surfaces

		·	
	Groups on Humic Substances	Groups and Sites on Mineral	Remarks
A. Primary interactions			
Cation bridging or inner-sphere bridging complexation Water bridging or outer-sphere bridging complexation	Anionic (carboxylate) and uncharged polar groups, such as amino, carbonyl, carboxyl, hydroxyl	Exchangeable cations at external basal surfaces. Also on the interlayer surfaces at low pH (<4.5)	Through weakly hydrated and non-hydrated monovalent cations. Through polyvalent cations in dehydrated system. Desorbable by Na salts Polyvalent cations in hydrated systems. Desorbable by sodium salts, water, and ultra-sonic
			treatment
Cation exchange	Positively charged nitrogen atoms	Acidic hydroxyl groups	Under acidic pH conditions
Proton transfer	Amine groups	Hydroxyl groups	Under acidic pH conditions
Anion exchange Ligand exchange	Carboxylate groups	Particle edge surfaces. Polyhydroxy compounds of Fe and Al at external, basal surfaces	Under acidic pH conditions and when exchange sites are occupied by Fe and Al ions. Desorbable by other anions in solution, such as chloride and nitrate When exchange sites are occupied by Fe and Al ions. In soils, on hydrous oxides of Fe and Al. Desorbable by other specifically and more strongly adsorbed anions, such as hydroxyl
B. Secondary interactions			
Hydrogen bonding	Amino, carboxyl, hydroxyl	Oxygen of external, basal (siloxane) surfaces	Weak
van der Waals	Uncharged portions of HS	Mainly at external, basal surfaces	Unimportant in hydrated systems but significant at high ionic strengths and in dehydrated systems. Short-range, weak but additive
C. Indirect interactions			
Entropy effects			Arising from entropy gain caused by displacement of many water molecules from the clay surface by a single humic molecule

The OM may further be physically protected from microbial attack by entrapment within nanopores of allophane aggregates (Dahlgren et al., 2004). The stabilization of OM through interaction with clay-size minerals will be further discussed below.

In acidic soils, HS may complex with short-range order minerals (allophane, Fe-(hydr)oxides), or with Al ions in the soil solution (Parfitt et al., 1999; Kleber et al., 2005; Mikutta et al., 2005). A quantitative relationship between pH and adsorption, however, is difficult to obtain. The species and concentration of cations in solution also affect adsorption. Yuan et al. (2000), for example, found that adsorption of humic acid by allophane increased with the concentration of Na⁺ or Ca²⁺ in solution, with Ca²⁺ being much more effective than Na⁺. Similar results were reported for illite (soil mica), montmorillonite, and kaolinite (Varadachari et al., 1991; Feng et al., 2005).

Assuming a supramolecular structure for soil OM, Kleber et al. (2007) have proposed a conceptual model in which HS interact with clay-size minerals in a discrete zonal sequence (Figure 2.3). The minerals are represented by a low-charge smectite, a 2:1 type phyllosilicate (e.g., illite) coated with Fe-(hydr) oxide, and an uncharged 1:1 type phyllosilicate (e.g., kaolinite) exposing a (hydrophobic) siloxane surface. In the contact zone, amphiphilic fragments of OM may adsorb to charged surfaces through electrostatic interactions, or ligand exchange with hydroxyls of Fe-(hydr)oxide coatings, directing hydrophobic portions outward to the aqueous solution. Proteinaceous materials, adsorbed to low-charge phyllosilicates, can serve as surface "conditioners," adding polar functionality to the hydrophobic siloxane portions on basal surfaces. Hydrophobic organics (e.g., phenanthrene) may also adsorb to the siloxane surface of uncharged minerals. The hydrophobic zone may

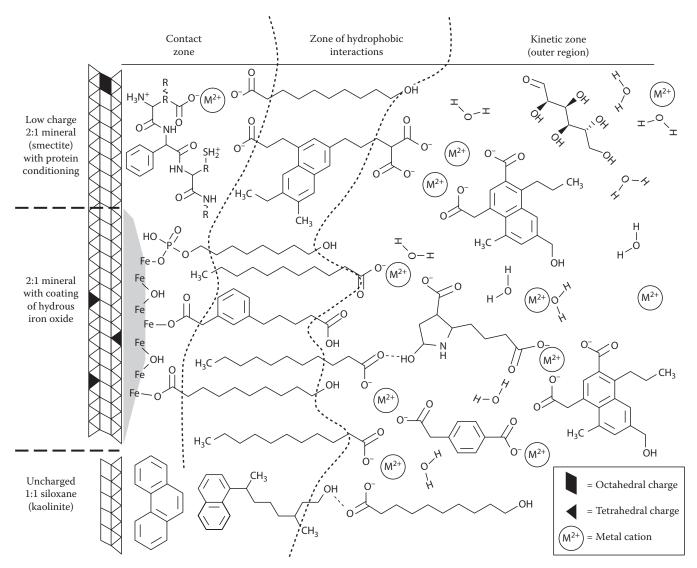

FIGURE 2.3 The zonal model of clay-organic interactions, details of which are given in the text. (Reprinted with kind permission from Springer Science+Business Media: Kleber, M., P. Sollins, and R. Sutton. 2007. A conceptual model of organo-mineral interactions in soils: Self-assembly of organic molecular fragments into zonal structures on mineral surfaces. Biogeochemistry 85:9–24.)

be discontinuous since the components here can exchange with the surrounding solution, while some proteins directly adsorbed on mineral surfaces may well expose ionized or polar functional groups to the solution. In the kinetic zone, the OM is loosely held by cation bridging, hydrogen bonding, and other interactions (Table 2.2). Thus, the thickness of the kinetic zone would depend on OM quality and is essentially controlled by exchange kinetics.

2.3.2 Methodologies for Investigating Clay-Organic Interactions

The clay-humic interaction may be investigated by several approaches (Cheshire et al., 2000). The "addition" approach in which HS are placed in contact with specific clay minerals is well documented (Theng, 1979; Schnitzer, 1986; Oades, 1989; Clapp et al., 1991; Schulthess and Huang, 1991; Stevenson, 1994). In the "separation" approach, the OM is removed from the clay by physical and chemical methods. The separated components are then characterized using various analytical and instrumental techniques. Physical separations include dry and wet sieving, slaking, ultrasonic dispersion, density or magnetic separation, and sedimentation (Elliott and Cambardella, 1991; Christensen, 2001). Chemical fractionation is based on the solubility of soil OM in water or organic solvents (e.g., *n*-hexane), the resistance of soil OM to oxidation, and dissolution of the mineral component by HF, dithionite-citrate-bicarbonate, or oxalate (Baldock and Nelson, 2000; Eusterhues et al., 2003).

The clay–humic interaction may also be probed directly, using solid-state 13 C NMR spectroscopy (Preston, 1996; Skjemstad et al., 1997), analytical pyrolysis (Schulten and Leinweber, 1996; Schulten et al., 1996), Fourier transform infrared (FTIR) and near-edge absorption fine structure (NEXAFS) spectroscopy, and scanning transmission x-ray microscopy (STXM) (Kaiser et al., 1997; Solomon et al., 2005; Kinyangi et al., 2006; Lehmann et al., 2007), or indirectly by measuring the SSA of soils by adsorption of N_2 gas at 77 K and applying the Brunauer–Emmett–Teller (BET) equation (Theng et al., 1999; Kaiser and Guggenberger, 2003).

Using FTIR and NEXAFS spectroscopy, Lehmann et al. (2007) found that the OC in $20\text{--}250\,\mu\text{m}$ microaggregates (of an Inceptisol and two Oxisols) was unevenly distributed, while the concentration of aliphatic carbon was well correlated with the amount of hydroxyl groups on kaolinite. X-ray microscopy and NEXAFS indicated that the complexity and occurrence of aliphatic carbon forms increased from the exterior to the interior regions of the microaggregate, while particulate OM was occluded in $2\text{--}5\,\mu\text{m}$ pores (Kinyangi et al., 2006).

Earlier, Kaiser and Guggenberger (2003) found that the $\rm N_2$ -BET surface area of a wide range of soils (under forest) decreased with increasing surface coverage by OM. This is because OM tends to occupy reactive sites on mineral surfaces (particle edges and dislocations) and "clogs" the openings of micropores, preventing $\rm N_2$ molecules from adsorbing to micropore surfaces. Such a discontinuous or "patchy" coverage of mineral surfaces by OM has also

been observed by several workers (Mayer and Xing, 2001; Chenu and Plante, 2006; Lehmann et al., 2007), and accords with the electron microscopy observation of marine sediments and soil nanoparticles (Ransom et al., 1997, 1998; Tang et al., 2009), and the x-ray photoelectron spectroscopic analysis of soil particles (Yuan et al., 1998).

Besides affecting the surface area of soils, the interaction of HS with soil mineral surfaces through ligand exchange causes the surface charge to become more negative as shown in Equation 2.1 for allophane. Further, OM bound by ligand exchange is more resistant to biodegradation than that held by cation bridging and van der Waals interactions (Mikutta et al., 2007). The effect of mineral surface wettability on OM decomposition will be described below.

2.3.3 Effects of Clay-Organic Interactions

The high reactivity of clay-size minerals toward water and organic compounds in soils (and sediments) is expected to influence biological processes in these environments. Indeed, the work by Müller and Höper (2004) indicates that the stabilizing effect of clay was more in evidence with respect to the microbial biomass than humus. The most important effect would be on the availability of water and substrate to microorganisms. As their metabolism requires water, microorganisms in soil are drawn to sites with a continual supply of water. Being able to retain water against gravity and adsorb organic molecules, clay-size minerals provide a favorable environment for microbial growth and survival (Theng and Orchard, 1995). More recently, Bachmann et al. (2008) have proposed that soil wettability may play an important role in OM stabilization as it controls the microbial accessibility to water, nutrients, and oxygen. The manner in which organic molecules are retained by clays will determine their bioavailability to microorganisms. At the same time, the attachment of clay particles to microbial cells would reduce the effective surface area of microorganisms for transmembrane transfer of nutrients and waste products.

2.3.3.1 Effect on Soil Structure and Aggregate Stability

Soil structure, as indicated by the stability of soil aggregates, is a key factor in the functioning of soil (Bronick and Lal, 2005). OM contributes to aggregate stability through (1) enhancing aggregate cohesion by binding soil particles together and (2) decreasing aggregate wettability by slowing the rate of wetting and extent of slaking (Sullivan, 1990). Aggregate stability is often correlated with soil OM content (Chaney and Swift, 1984; Golchin et al., 1995; Chenu et al., 2000). However, whether there is a defined threshold value below which aggregate stability will decline is still open to question (Loveland and Webb, 2003). Polysaccharides excreted by plant roots and microbial cells can bind small aggregates (<20 µm) into macroaggregates (Theng, 1979; Swift, 1991; Figure 2.1). The effectiveness of polysaccharides, however, tends to be short-lived because these compounds are readily decomposed by microorganisms (Tisdall and Oades, 1982). On the other hand, HS can provide long-term stability to microaggregates (Guckert et al., 1975; Kay and Angers, 2000). Their beneficial effect may be ascribed to the formation of clay-organic complexes by which the anionic groups of HS are oriented toward the interior of the microaggregates, while the hydrophobic components face outward (Piccolo et al., 1997; Figure 2.3). In line with this suggestion, Capriel et al. (1990) observed that the aliphatic fraction of soil OM (extractable with supercritical hexane) was highly correlated with aggregate stability, probably because this hydrophobic material could form a water-repellent "screen" around the aggregates. Similarly, Shepherd et al. (2001) found that the high aggregate stability of an allophanic soil (under long-term cropping) was related to the concentration of polymethylene (alkyl) carbon in the clay fraction. The strong binding of allophane to OM during cropping can confer great stability on HS, thereby arresting further decline in soil OM (Theng and Tate, 1989).

The relationship between OM composition (determined by FTIR spectroscopy), soil wettability (derived from contact angle measurements), and aggregate stability has recently been discussed by Bachmann et al. (2008). Although the coverage of clay-size minerals by OM is patchy, OM can form microaggregates with metal hydr(oxides) and phyllosilicates, and becomes stabilized against microbial decomposition. As the hydrophobicity of the OM increases, the wettability of such microaggregates decreases and their stability is enhanced.

OM as such, or in association with clays, has a positive effect on many other soil physical properties, such as compactability, tillage, friability, tilth, and hard-setting (Ball et al., 2000; Dexter, 2004a, 2004b; Watts et al., 2006). Improvements in such soil physical properties as bulk density, structure, water retention, and content of readily dispersible clay correlates better with clay-associated OM than total carbon content (Dexter et al., 2008).

The clay-organic interaction may occasionally cause soils to become water-repellent. Water repellency occurs when the surface of mineral particles is covered by a film of hydrophobic organic materials (e.g., waxes). This condition can be found in loamy, clayey, peat, and volcanic ash soils (Wallis and Horne, 1992), and even in sandy soils (Franco et al., 2000). Water repellency can reduce water infiltration, enhance surface runoff and erosion, induce the formation of preferential flow patterns in soil, and decrease plant growth. In the absence of a universally applicable solution to water repellency, a number of soil management practices have been proposed to reduce its impact. These include the use of surfactants to reduce surface tension, clay to cover and encourage degradation of hydrophobic surface, water harvesting, and reduced soil drying (Blackwell, 2000).

2.3.3.2 Effect on Organic Matter Dynamics and Turnover

Organic matter in soil consists of a wide range of organic molecules that are stabilized by different mechanisms and have variable turnover rates. Models of soil OM turnover are often based on conceptual pools with turnover rates ranging from less than a year to thousands of years. Terms such as "active," "slow," "passive," and "inert" have been used to describe the relative stabilities of the various functional OM pools. The active pool

with turnover rates of less than 10 years is associated with the microbial biomass and "light fraction" (density <1.6–2.0 g cm⁻³). Most chemical and physical fractionation methods, however, do not yield homogeneous fractions in terms of turnover rates. The conceptual passive pool, in which the majority of soil OM is stabilized, is especially difficult to isolate (von Lützow et al., 2007).

Earlier, Parfitt et al. (1997) compared OM turnover in an Andisol, containing allophane and imogolite, with that in an Inceptisol having mica as the main clay mineral species. Under long-term pasture, the Andisol (0-20 cm) accumulated 144 Mg ha-1 of OC, which was twice as much as the Inceptisol. After 20 years of cropping, the Andisol lost 10 T ha-1, representing half the quantity that was lost from the Inceptisol. It would therefore appear that the turnover of carbon was much slower in the Andisol than in the Inceptisol. The most likely mechanism for the slower turnover of soil OM in the allophanic soil could be the stabilization of the microbial biomass and microbial metabolites (Saggar et al., 1994). Modeling (with CENTURY) further indicated that the pool of passive OM in the Andisol was very large. Basile-Doelsch et al. (2007) also found that the minerals of a volcanic soil (in La Réunion) could store large amounts of OM with a very long turnover time. Similar results were reported for some temperate forest soils containing short-range order minerals (Eusterhues et al., 2003; Kögel-Knabner et al., 2008; Rasmussen et al., 2008). In reviewing the literature on stabilization of OM in temperate soils, von Lützow et al. (2006) have concluded that molecular recalcitrance is only important in surface soils during early decomposition. In subsoils and during late decomposition, however, OM is largely stabilized through spatial and physical inaccessibility (occlusion, intercalation, encapsulation) and interactions with mineral surfaces.

The recent extension of single layer models of soil OM turnover to include deeper layers in the soil profile (Jenkinson and Coleman, 2008) provides a reasonable fit between measured and modeled soil C and radiocarbon age for some soils, but not necessarily in soils with clay-rich subsoils. Accounting for the capacity of different clay types and contents to stabilize soil OM pools is still needed to improve such models for use across a range of different soil types.

2.3.3.3 Effect on Nutrient Dynamics

Soil OM is a large reservoir of carbon as well as nitrogen, phosphorus, and other elements that are essential to life. Globally, soils contain 1462–1548 Pg of OC and 133–140 Pg of nitrogen in the upper 100 cm of their profiles, while the mean C:N ratios of soil OM ranges from 9.9 (for arid Yermosols) to 25.8 for Histosols (Batjes, 1996). As most nitrogen in soil is in organic form, soil OM is a huge reservoir of N in comparison with the amount of N that is annually "fixed" by lightning (<10 Tg; 1 Tg = 10^{12} g), by (leguminous) crops (32–53 Tg), and by fertilizer additions (80 Tg in 1992) (Galloway et al., 1995; Vitousek et al., 1997). The amount of N in soil OM is also much greater than that held in (above-ground) vegetation (~10 Pg) (Davidson, 1994). In most terrestrial biomes and many marine ecosystems, net primary production is often limited by nitrogen supply (Vitousek and

Howarth, 1991), and there is a limit of nitrogen fertilizer that can be added to soil without causing adverse impact on water quality. Thus, the importance of soil organic nitrogen to primary production cannot be overstated. Besides being an inexpensive, benign, and reliable source for crop production and forest growth, soil organic nitrogen has long-term availability through interaction with the clay fraction.

The cycling of (organic) nitrogen is closely linked to that of carbon (McGill and Cole, 1981) because most of the nitrogen in OM is bound to carbon. Nitrogen mineralization in soil is primarily driven by the need of microorganisms for carbon. When nitrogen is mineralized, the associated carbon is oxidized to CO₂. In natural systems, the movement of nitrogen from soil to water is mediated by dissolved organic carbon (DOC), most of which originates from plant litter and humus (Kalbitz et al., 2000). A carbon-13 tracer study by Hagedorn et al. (2004) suggests that in forest soils DOC is produced during incomplete decomposition of recalcitrant native carbon. This is because easily degradable carbon components are rapidly consumed by microbes and hence make only a minor contribution to the dissolved carbon fraction.

2.3.3.4 Impact on Sorption and Bioavailability of Heavy Metals and Organic Contaminants

The dynamics and fate of environmental contaminants in soil are greatly altered by their reactions with clay, HS, and clayhumus complexes. Negatively charged phyllosilicates and HS can sorb heavy metal cations through electrostatic interactions (cation exchange), while sorption to short-range order minerals (allophane), Fe-, Al-, and Mn-(hydr)oxides, and the edge surface of phyllosilicates largely occurs through ligand exchange, giving rise to inner-sphere complexes. This process is distinguishable from cation exchange by a high degree of specificity, a tendency for irreversibility, and a shift of the point of zero charge to more positive values (McBride, 1994). Ligand exchange (see Equation 2.1) is also the dominant mechanism underlying the sorption of heavy metal anions (e.g., arsenate) by clay-size soil minerals and HS (Arai et al., 2005; Violante et al., 2008).

Clay-organic interactions affect the mobility and bioavailability of heavy metals in soil by (1) changing the kinetics of metal sorption and desorption and (2) altering the dispersibility of clay particles and OM. As already mentioned, HS (in clayorganic complexes) occupy reactive sites on mineral surfaces and "clog" the openings of micropores. As a result, both the sorption of metal ions to the complex and their diffusion within clay aggregates are diminished. Since desorption is also retarded, the bioavailability of sorbed heavy metals is reduced. Bioavailability also decreases as the contaminant-soil contact time increases. The "aging" effect may be ascribed to slow diffusion of the contaminant molecules into micropores and long-term changes in solute-surface mode of bonding (Chorover et al., 2007). Metal ions in soil may also associate with the soluble fractions of OM (e.g., fulvic acid and DOC). Sorption of these mobile organic colloids to clay-size minerals decreases clay dispersibility as well as the mobility of the associated metal contaminants (Kretzschmar and Schäfer, 2005; Hochella et al., 2008). As a result, leaching of heavy metals from soil to adjacent water bodies is reduced.

The clay-organic interaction also exerts a controlling influence on the sorption of organic contaminants. The correlation of sorption with soil OM content is especially pronounced for nonionic (hydrophobic) organic solutes. Indeed, the sorption of many organic compounds of low polarity to organic-rich topsoils gives rise to linear isotherms and can be rationalized in terms of simple partitioning into OM (Chiou, 1989). This process is akin to solute extraction from water into an organic solvent, such as 1-octanol. In general, however, the sorption of nonionic organic compounds gives rise to curvilinear isotherms, and conforms to the Freundlich equation (e.g., Xing and Pignatello, 1998). The retention of such contaminants (e.g., pesticides, polycyclic aromatic hydrocarbons) by soils with different OC contents may be predicted by the following equation:

$$\log K_{oc} = a + b \log K_{ow}$$
 (2.2)

where

 $K_{\rm oc}$ is the organic carbon-normalized sorption coefficient $K_{\rm ow}$ is the octanol-water partition coefficient of the organic contaminant

a and b are empirical constants

In many instances, however, K_{oc} of organic contaminants cannot be derived from the corresponding K_{ow} value because of differences in the quality (aromaticity and polarity) of soil OM (Xing, 1997).

Besides controlling the sorption of organic contaminants in soil, the clay-organic interaction also influences the decomposition and bioavailability of organic contaminants. Thus, sorption and desorption are slow because the organic solute must diffuse through soil OM matrices and intraparticle micropores (Pignatello and Xing, 1996). By promoting aggregate formation and stability, the clay-organic interaction provides a favorable environment, in terms of water and substrate requirements, for microbial decomposition of organic contaminants. Rhodes et al. (2008), for example, reported that the rate and extent of phenanthrene degradation in natural soils was higher than in an artificial soil (comprising 70% fine quartz sand, 20% kaolinite, and 10% fine powdered Sphagnum peat), with a comparable sorptive capacity. This might be because the artificial soil lacks stable aggregates where both microorganisms and contaminant reside, allowing for microbial growth and degradation to proceed (Harms and Zehnder, 1995). In other words, the simultaneous enrichment of contaminants and microbes in clay-organic complexes promotes biodegradation. The bioavailability of the contaminants, associated with clay-OM complexes, has been reviewed by Feng and Boyd (2008). As might be expected, the process is influenced by the nature of both contaminant and sorbent. Aging is another important factor in that contaminant bioavailability generally decreases with time.

2.3.3.5 Impact on Greenhouse Gas Emission

Since soils are an important carbon sink, the clay-organic interaction has also attracted the attention of climate change researchers. In temperate, cultivated soils, 50%-75% of the OM exists as clay-organic complexes (Christensen, 2001), while in volcanic soil horizons up to 83% of the OM is associated with mineral surfaces (Basile-Doelsch et al., 2007). Global warming would accelerate the decomposition of mineral-associated OM in soil because the process is temperature-dependent (Lloyd and Taylor, 1994; Davidson and Janssens, 2006). An increase in temperature would therefore act as a positive feedback in the global carbon cycle (Kirschbaum, 1995). On the other hand, Liski et al. (1999) and Jenkinson and Coleman (2008) have suggested that the extent of CO₂ emission from soil in response to climate warming is overestimated, while Giardina and Ryan (2000) have gone so far as to say that the decomposition of OM in forest soils is independent of temperature. The apparent inconsistencies in data reporting and interpretation partly arise from conceptual differences regarding the nature of OM or OC, and the use of single-layer models of soil OC turnover. Further, due caution must be exercised in extrapolating results from short-term laboratory studies (often involving microbes) to long-term impacts at a global scale. For example, the availability of water and organic substrates to microbes during OM decomposition (Gershenson et al., 2009) is an important factor affecting the movement of carbon from soil to the atmosphere. Equally relevant is the finding that the stabilizing effect of clay is apparently much stronger for the microbial biomass than for humus (Saggar et al., 1994; Müller and Höper, 2004). Similarly, Ekschmitt et al. (2005) have suggested that ecological limitations inherent to soil life, such as specialization of organisms with respect to microhabitats and substrates, contribute to lowering decomposition rates and preserving OM in temperate soils.

As already mentioned, there is general agreement that interaction with clays can protect OM in soil from microbial decomposition (e.g., Chenu and Plante, 2006). The protective effect of clays is especially important for soils of tropical regions where climatic conditions favor decomposition (Wattel-Koekkoek et al., 2001). Working with two acid forest soils, Eusterhues et al. (2003) found that the stable fraction of OM with an old radiocarbon age comprised 1%–30% of the total OC in surface horizons, and up to 80% in the subsoil. The stability of the old ("passive") OC was ascribed to interaction with clay mineral and/or iron hydr(oxide) surfaces. Marschner et al. (2008) have come to the same general conclusion saying that "black carbon" and "fossil carbon" may be the only type of OC that can persist in soil without being associated with minerals.

A rather unique example of OM preservation comes from the work by Theng et al. (1986, 1992) who were able to isolate an interlayer clay-organic complex from the surface horizon of a Spodosol. Here the OM was intercalated into a swelling mixed-layer 2:1 type clay mineral and hence was physically protected from microbial attack, giving a radiocarbon age of 6700 years BP. Protection by intercalation into expansible phyllosilicates is

uncommon, however (Eusterhues et al., 2003; von Lützow et al., 2007). This is because interlayer complex formation requires a combination of soil factors that is only rarely encountered (Theng et al., 1986).

It is also difficult to establish a quantitative relationship between clay content and OC. Many researchers have found that soil OC content correlates positively with clay content (e.g., Nichols, 1984; Van Veen et al., 1984). On the other hand, Percival et al. (2000) failed to detect such a correlation for New Zealand grassland soils. Instead, they found that pyrophosphate-extractable Al alone or in combination with allophane, Fe-(hydr)oxide, and clay could account for much of the variability in soil carbon contents. Similarly, Müller and Höper (2004) observed a very weak relationship between the concentration of humus carbon and clay content. A recent study of the capacity of soils to store carbon (Kool et al., 2007) shows that there is a hierarchy in C saturation across different soil OM pools exposed to elevated atmospheric CO₂. In this example, there was a shift in the allocation of C from small to large aggregates, leading to the conclusion that soil can become saturated with C, probably because of a limit to physical protection of OC. The effect of clay content and type has been included in some national scale models (Tate et al., 2005). Using a combination of factors such as soil type and climate as model parameters, these models allow changes in soil C with land use change to be simulated.

2.4 Conclusions and Perspectives

The interaction of clay with OM in the soil environment is a ubiquitous natural process and underpins a range of essential ecological services and functions, from regulating water storage and nutrient cycling, through adsorbing and transporting metal and organic contaminants, to serving as a source or sink of OC and greenhouse gases. Until the early 1980s, the focus of research was on the interaction of well-defined small and polymeric organic molecules with specific crystalline clay minerals. Attention has since turned to more complex soil systems where many kinds of minerals, organic substances, and microbes coexist under different environmental conditions. The participation of nanosize short-range order minerals and metal (hydr)oxides, as well as microorganisms, in the interaction process is duly recognized. Also, the concept of HS being a mixture of high-molecular-weight linear polymers, adopting randomcoil conformations in solution, has evolved to one of an assembly of low molecular weight, biologically derived molecules held together by weak dispersive forces, forming micelles in solution. As already remarked, however, the two concepts may not be mutually exclusive. Enzymes and clays can catalyze the polymerization and/or polycondensation of low-molecular-weight biomolecules, giving rise to dark-colored humic-like polymers. At the same time, unstable biological molecules and residues may be preserved by incorporation into, and encapsulation by, polymeric humified materials.

Clay-size minerals in soil (phyllosilicates, short-range order alumino-silicates, metal (hydr)oxides) can interact with HS through different modes of bonding, the relative importance of which would vary from soil to soil, and within a given profile, from top to bottom. In temperate soils, for example, the proportion of OC bound to clay-size minerals increases with soil depth as does bonding strength. Microorganisms participate in this process in that the clay-humus complex provides substrates and protection to soil microbes. In excreting polysaccharides and proteins, microorganisms also contribute actively to the clay-organic complex formation (Kögel-Knabner et al., 2008). The clay-organic interaction affects a range of soil properties and functions, including structure (aggregate stability), OM turnover, and nutrient dynamics, as well as the behavior and fate of heavy metals and organic contaminants.

Soil is also an important source and sink of greenhouse gases. By its very nature, the clay-organic interaction would be expected to affect the emissions of greenhouse gases from soil. We have no clear understanding, however, about the operative mechanisms involved. Models of soil carbon dynamics, for example, do not usually account for the capacity of different clay-size mineral species to stabilize OM in various pools. This gap in knowledge needs to be filled in order to store more carbon in soil, reduce greenhouse gas emission from soil, and appreciate the effect of climate change on soil functions.

The quantitative relationship between OM, clays, and environmental conditions, on the one hand, and the extent and rate of OM stabilization in soil, on the other hand, still needs to be clarified. In temperate soils, pedogenic Fe-(hydr)oxides appear to be the principal clay-size minerals involved in the sorption and stabilization of OM, especially in the subsoil. Because of the "patchy" surface coverage by OM, however, total surface area and micropore volume do not generally correlate with the amount of mineral-associated OM (Kögel-Knabner et al., 2008).

No universally applicable relationship has been established between soil OM dynamics and the quantity of various clay-size mineral species. This is because such a relationship is influenced by many variables. Many studies, based on laboratory incubations and statistical analysis, have shown that the content of OM and microbial biomass in soil is positively correlated with that of clay (Nichols, 1984; Kern, 1994; Saggar et al., 1994; Alvarez and Lavado, 1998; Homann et al., 1998). Accordingly, clay content features strongly in a number of soil OM models that have been developed to assess the impact of climate change on soil OM and subsequent feedback effects (e.g., Smith et al., 1997). Other investigators (Percival et al., 2000; Eusterhues et al., 2003; Kleber et al. 2005; Rasmussen et al., 2006), on the other hand, have suggested that short-range order minerals and aluminum are more important than layer silicates in stabilizing OM in soil. Similarly, Spielvogel et al. (2008) have found that OM associated with (oxalate-extractable) Al and Fe is potentially stable for thousands of years.

It would appear that both the quantity and quality of claysize minerals in soil play a part in OM stabilization and hence should be taken into account in modeling soil OC dynamics. Likewise, the underlying mechanisms need to be considered in quantifying the protective capacity of soil for OM (Baldock and Skjemstad, 2000). The characterization of the mineral and OM constituents in specific soil fractions, combined with measuring turnover times and soil age would also merit further investigation (von Lützow et al., 2006; Kögel-Knabner et al., 2008). Another topic for future research is the contribution of electron donor–acceptor interactions to the sorption affinity of organic compounds and pollutants containing aromatic moieties and hence to the stability of soil OM against microbial decomposition (Keiluweit and Kleber, 2009).

3.1 Introduction: Nanoscience and Nanotechnology

Nanoscience and nanotechnology together represent one of the "hottest" research areas in science and engineering at the start of the twenty-first century. With new advances in instrumentation and theory, scientists have come to realize that within the range of 1 to ~100 billionths of a meter, known as the nanoscale, materials may display properties and behaviors that are unique and often cannot be described using our knowledge of either bulk systems or individual molecules. This is not necessarily a surprise to soil scientists who have known for many decades that fine-grained soil minerals such as aluminosilicate clays and ferrihydrite tend to have special properties that are distinct from those of larger minerals. The soil science community also has taken a leadership role in understanding the structures and behaviors of complex nanoscale organic matter components such as humic and fulvic acids.

Many of the natural constituents of soils are nanoparticles—for example, aluminosilicate clays, Fe(hydr)oxides such as ferrihydrite, viruses, and humic substances. Soil nanoparticles may occur as mobile colloids (Kretzschmar and Shäfer, 2005), as coatings on other mineral surfaces, and/or as mixed organic/inorganic aggregates (Nugent et al., 1998; Chorover et al., 2007). The high surface areas of nanoparticles mean that they are

particularly influential in controlling the fate and transport of pollutants as well as the bioavailability of key nutrients such as phosphate and Fe (Brown and Parks, 2001; Hochella et al., 2008; Theng and Yuan, 2008). Nanoparticles interact with soil microorganisms at a profound level. Microbial processes are key to both the nucleation and dissolution of Fe and Mn (hydr) oxides (Banfield and Zhang, 2001; Fortin and Langley, 2005) and there have even been reports of biogenic uraninite nanoparticles (Bargar et al., 2008). Synthetic nanoparticles are finding their way into the environment, and how they interact within soils is a key topic of international concern and research (EPA, 2005; Nowcak and Bucheli, 2007).

Nanoparticles are important not only in soils per se but also in the broader near-earth-surface environment known as the critical zone (Hochella et al., 2008; Maurice and Hochella, 2008). Nanoparticles are ubiquitous in aquatic and marine environments, often controlling pollutant transport and nutrient bioavailability. For example, Fe oxide nanoparticles are likely to be a major source of essential Fe to ocean algae, helping to control ocean biological productivity and ultimately the global carbon cycle (Wu et al., 2001). Nanoparticles in surface waters, soils, and aquifers often control the mobilities of pollutants such as heavy metals, radionuclides, and hydrophobic organic compounds (Brown and Parks, 2001). Nanoparticles play a major role in the transport of toxic metals in acid mine drainage environments

(Hochella et al., 2005). Nanoscale precipitates may form on mineral surfaces, helping to control reactivity but often eluding detection and/or characterization by most conventional microscopic and spectroscopic techniques (Nugent et al., 1998). The nanotechnology industry is producing an increasing number of new nanomaterials such as fullerenes and synthetic ${\rm TiO_2}$ that are being introduced into thousands of products from cosmetics to targeted drugs to video display screens and finding their way into the environment. Yet, we know very little about the environmental consequences of these materials (NRC, 2008). On the other hand, nanotechnology offers new opportunities for "green" water purification (i.e., with low energy consumption; Shannon et al., 2008) and is leading to an advanced generation of nano-enabled environmental sensors (Potter et al., 2007).

3.1.1 Chapter Goals

This chapter aims to describe our state-of-the art—though rapidly changing-understanding of what makes nanomaterials unique, to provide insight into the special behaviors of nanomaterials, and to highlight how the soil science community can both benefit from and contribute to nanoscale environmental research. A key underlying principle in this chapter is that the high surface areas of nanoparticles mean that their characteristics, including stabilities and reactivities, can be extremely sensitive to surface free energy. Nanoparticles have a relatively high proportion of atoms associated with their surfaces. These surface- and near-surface atoms have different coordination environments than in analogous bulk materials. Nanoparticles may have different surface composition, different types and densities of surface sites, and different reactivities with respect to processes such as sorption, catalysis, and redox reactions (Waychunas et al., 2005). Nanoparticles also may have different overall crystalline order or structure, different stability, and unique thermal, optical, electrical tensile strength, and/or magnetic properties than observed in larger, bulk materials. We are only beginning to understand the controls on the fundamental properties of nanoparticles; how they behave in complex soil environments is even less well understood.

3.1.2 Nanoparticles and Nanominerals

A nanometer is one billionth (10⁻⁹) of a meter and the prefix "nano" is used to encompass materials and processes at this general scale. The term "nanoparticle" is used throughout this text, although its definition has been subject to much debate and continues to evolve. One common definition of a nanoparticle is any ultrafine particle that is between 1 and 100 nm in size. This size limit is sometimes applied to just two dimensions. Under this definition, various nanoparticles may or may not have properties that differ from those of larger, bulk materials. Banfield and Zhang (2001) suggested that the upper limit to the size of a nanoparticle might be defined based on the size at which fundamental properties differ from those of a corresponding bulk material. According to this definition, the maximum size

range for a nanoparticle is likely to vary for different materials. Hochella et al. (2008) suggested that the size range in which particles of earth materials behave differently is often between one and at most several tens of nanometers.

Hochella et al. (2008) defined nanominerals as minerals such as ferrihydrite that exist only in the nanoparticle size range, or clays that only exist with at least one nanoscale dimension. These authors defined mineral nanoparticles as minerals that are in the nano-size range, but that also exist at larger sizes. Most known minerals probably can and do exist somewhere in nature within the nanoparticle size range, although we are beginning to learn that some minerals may be differently hydrated or undergo other compositional or structural changes at small particle size so that new mineral nomenclature may need to be defined in some instances. In any case, nanominerals challenge the common definition of a mineral as "a naturally occurring homogeneous solid with a definite (but generally not fixed) chemical composition and a highly ordered atomic arrangement" (Klein and Hurlbut, 1985), because composition, structure, and especially physical properties all can change at the nanoscale.

Nanoparticles overlap in size with colloids, which range in diameter from 1 nm to 1 μm (Buffle, 2006; Figure 3.1). Nanoparticles are often included in the dissolved fraction of solution samples, as defined by passage through a 0.45 μm filter, even though nanoparticles are distinct in structure, properties, and reactivity from molecules and ions. Nanoparticles often form as secondary minerals during the weathering of larger particles, for example, kaolinite on feldspar. Such surface adhered nanoparticles can be difficult to detect and characterize by conventional means such as scanning electron microscopy (SEM) and microprobe analysis, but can potentially impact reactivity with respect to adsorption and dissolution (Nugent et al., 1998).

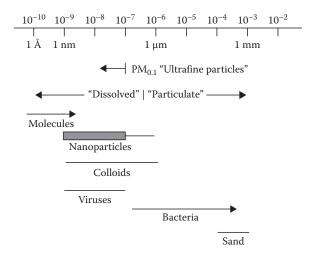

FIGURE 3.1 The size ranges of some environmental particles, including nanoparticles. The box for nanoparticles indicates that nanoparticles are 100 nm or less in at least two dimensions, but can be longer in the third dimension (such as nanotubes and nanowires). (From Maurice, P.A. 2009. Environmental surfaces and interfaces from the nanoscale to the global scale. Wiley, Hoboken, NJ.)

3.1.3 Natural and Engineered Nanoparticles

Soils are in a sense the ultimate nanoenvironments. Nanominerals, mineral nanoparticles, and many nonmineral nanoparticles are commonly found in soils (Hochella et al., 2008; Theng and Yuan, 2008). Viruses generally occur as nanoparticles, and bacteria may contain nanoscale features such as cilia and flagella. Microorganisms may play a role in the formation of a wide variety of nanobiominerals or biomineral nanoparticles, such as Fe and Mn (hydr)oxides and carbonates. According to Tebo et al. (1997) microorganisms appear to be responsible for most Mn(II) oxidation in the environment, and hence they play a dominant role in the formation of Mn oxides, which primarily form as high surface area nanoparticles. The role of microorganisms in the formation of carbonate nanoparticles (Figure 3.2) is receiving a great deal of attention, particularly regarding controls on the carbonate polymorph structure, micromorphology, and microtopography (Warren et al., 2001). Humic substances tend to occur within the nanoscale size range (Figure 3.3; Maurice and Namjesnik-Dejanovic, 1999; Namjesnik-Dejanovic and Maurice, 2001), and their composition, structure, properties and behaviors have long challenged the environmental geochemistry/soil chemistry communities. Black carbon, which forms from the incomplete combustion of fossil fuels, may occur in the nanoscale size range or larger, and is present in many soil environments (Hedges et al., 2000). Given that black carbon tends to be highly unreactive with respect to oxidation, it may represent an important sink of carbon in the global carbon cycle (Kuhlbusch and Crutzen, 1995).

Engineered nanoparticles are becoming increasingly widespread in the environment, and their potential impact on soil and plants is only beginning to be considered (e.g., Nowack and Bucheli, 2007). The U.S. Environmental Protection Agency (EPA, 2005)

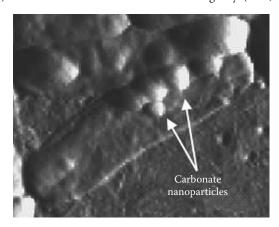

FIGURE 3.2 In-air AFM image of carbonate nanoparticles formed on the surface of *Bacillus pasteurii*. The microbe in the central region of the image is approximately 2.8 μm long and was deposited from solution on polycarbonate membrane filter. Microorganisms play important roles in the formation of mineral nanoparticles and nanominerals. The sawtooth pattern along the edge of the bacteria is an artifact. The experimental conditions are described in Warren et al. (2001). (From Warren, L., P. Maurice, N. Parmar, and G. Ferris. 2001. Microbially mediated calcite precipitation: Implication for solid-phase capture of inorganic contaminants. Geomicrobiol. J. 18:93–115.)

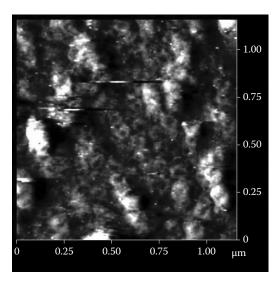

FIGURE 3.3 In-solution AFM image of surface water fulvic acid on muscovite in $0.01\,\mathrm{M}$ CaCl₂ at pH 5. Some nanoscale structures and porosity are apparent. Sample preparation and imaging parameters as described by Maurice and Namjesnik-Dejanovic (1999). (From Maurice, P., and K. Namjesnik-Dejanovic. 1999. Aggregate structures of sorbed humic substances observed in aqueous solution. Environ. Sci. Technol. 33:1538–1540.)

describes four categories of intentionally manufactured nanoparticles. These are: carbon-based materials such as the fullerenes and carbon nanotubes; metal-based materials such as quantum dots and nano-silver along with reactive metal oxides such as zinc oxide (ZnO) and titanium dioxide (TiO₂); dendrimers, which are nanopolymers constructed of branched units; and nanocomposites. Nanoparticles also may be manufactured unintentionally as a result of grinding, combustion, and other processes.

Gold nanoparticles were used in medieval times in stain glass window production. Nanoparticulate (3.5–100 nm) gold suspensions in water create an intense red color due to plasmon absorption (Brust and Kiely, 2002). Nanoparticulate gold has become the subject of broad industrial interest due to strong catalytic capabilities (Brust and Kiely, 2002). Thiol-stabilized gold nanoparticles may self-assemble into superlattices (Giersig and Mulvaney, 1993) whose change in conductivity in the presence of different organic vapors has led to the development of novel gas sensors (Wohltjen and Snow, 1998). Silver nanoparticles are being widely used as bactericides (Brust and Kiely, 2002). TiO₂ nanoparticles are used in a wide array of applications, including heterogeneous catalysis, photocatalysis, in solar cells for the production of hydrogen and electric energy, gas sensing, pigmentation (paints and cosmetics), sunscreen, protective coatings, and electronics applications (Diebold, 2003).

Discovery, characterization (Kroto et al., 1985), and eventual engineering of fullerenes helped to ignite the nanotechnology revolution. Like many nanomaterials, the definition of the word "fullerene" is subject to some debate and is evolving. Fullerenes are allotropes of carbon, the most famous of which, Buckminsterfullerene, has the formula C_{60} and is about 1 nm in diameter (Figure 3.4). Fullerenes can occur naturally, and have been found in C-rich metamorphic rocks known as shungite

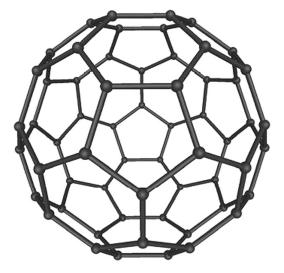

FIGURE 3.4 The structure of C_{60} fullerene, Buckminsterfullerene. The structure of C_{60} resembles a soccer ball consisting of 20 hexagons and 12 pentagons, with a C atom at each vertex and a bond along each polygon edge. (From Wikimedia commons, http://commons.wikimedia.org.)

(Buseck et al., 1992; Parthasarathy et al., 1998); in rocks that have experienced lightning strikes (Daly et al., 1993) or meteorite impacts (Becker et al., 1994), and even in rocks associated with the cretaceous-tertiary (K/T) boundary (Heymann et al., 1994). Fullerenes may occur not only as "buckeyballs" but also as nanotubes, nanosheets, and in other structures, sometimes aggregated. They tend to be insoluble in water, but may be surface functionalized in ways that can greatly affect their solubility, adsorption, aggregation, and other properties.

There are many fundamental questions about the potential impacts of manufactured nanoparticles such as fullerenes on soil and agricultural environments. For example, what are the controls on fullerene mobility in different soil media? What controls fullerene aggregation and how may aggregation affect mobility? What are the potential short- and long-term ecotoxicity effects of fullerenes? How might fullerenes affect soil microbial communities? Are fullerenes taken up by plants? If so, then what are the potential consequences for human health? What are the long-term stabilities of different fullerenes, including various functionalized forms, and how might degradation impact fate and transport, ecotoxicity, and other considerations? In order to begin to answer such questions, it is important to understand that fullerenes and other nanoparticles generally show unique properties and behaviors related to their small size and characteristic high surface area.

3.2 Nanoscience Is Changing Our View of the Properties and Behaviors of Nanoparticles

The large amount of attention and funding focused on nanoscience and technology over the past two decades has led some to question whether it is all just "nano-hype" (Berube, 2005). As will be demonstrated in this chapter, there are real differences in the properties

and behaviors of nanoparticles versus ions and molecules or larger, bulk-scale materials, so that the nanoscale represents a true frontier for revolutionary research in science and engineering.

Much of our past understanding of the properties and behaviors of small particles developed over many decades through traditional approaches in (surface) chemistry and physics. Yet, through recent developments in new nanoscale techniques and approaches, we are learning that many nanoparticles and nanoscale processes do not conform to long-held theories and conceptions. In this section, we compare and contrast classical theories and approaches of size, stability, and reactivity with our new and evolving nanoscale understanding.

3.2.1 Nanoparticle Size and Structure

The classical means of determining the structure of a crystalline material is by x-ray diffraction (XRD) as part of x-ray crystallography. Based on a diffraction pattern, the crystallographer can determine detailed information about the mean positions of atoms in a crystal, chemical bonds, and degree of disorder. However, single-crystal XRD, which is the best method for determining structure, is not feasible for nanoparticles because of their small size.

Although it can be difficult to determine nanoparticle structure by classical XRD alone, a number of other techniques can be helpful, particularly when applied in combination. High-resolution transmission electron microscopy (HRTEM) and scanning transmission electron microscopy (STEM) can help in determining whether particles are crystalline or amorphous. The TEM image in Figure 3.5 shows ~10 nm diameter hematite nanoparticles with lattice fringes indicating an ordered crystalline structure.

Other techniques that can be helpful for determining the structure and/or composition of nanoparticles include synchrotron-based x-ray absorption spectroscopy (XAS) and x-ray scattering methods coupled with pair distribution function (PDF) analysis. PDF can allow for determination of changes in interatomic distance as a function of radius, composition, and other

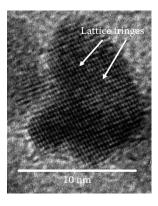

FIGURE 3.5 TEM image of hematite nanoparticles showing lattice fringes. Nanoparticles often are not fully amenable to XRD analysis, and TEM can be essential for determining structure and order. (From Barton, L.E., K.E. Grant, T. Kosel, A.N. Quicksall, and P.A. Maurice. 2011. Size dependent Pb sorption to nanohematite in the presence and absence of a microbial siderophore: Effects of experimental design on sorption edges. Environ. Sci. Technol. 45:3231–3237. Copyright in press American Chemical Society.)

factors, thus providing enhanced analysis of not just short- and long-range structure but also composition and morphology.

For decades, soil scientists and mineralogists have pursued the structure of the Fe hydroxide nanomineral ferrihydrite. Ferrihydrite generally occurs as particles <10 nm, although often aggregated, is poorly ordered, and can have variable structural order. Ferrihydrite is generally designated 2-line or 6-line depending upon the number of reflections that appear in x-ray diffractograms as order increases. Ferrihydrite is not only of interest to the environmental community but also to the biomedical community. This is because ferrihydrite forms the core of the important Fe storage protein, ferritin (Pan et al., 2009). Hence, there is tremendous interest by the broad scientific community in determining the structure of ferrihydrite.

Recently, Michel et al. (2007a, 2007b) suggested that ferrihy-drite nanoparticles 6–2 nm in size all have the same composition (Fe $_{10}O_{14}(OH)_2$) and structure described by the hexagonal space group P6(3)mc. As particle size decreases from 6 to 2 nm, there is evidence of increasing disorder and distortion of some sites. Michel et al. (2007a, 2007b) showed that for 6 nm particles, the hexagonal unit cell dimensions $a \sim 5.95$ Å and $c \sim 9.06$ Å and the structure contains 20% tetrahedrally and 80% octahedrally coordinated Fe. For 2 nm particles, the hexagonal unit cell dimensions decrease slightly and some of the Fe sites have lesser site occupancy or show evidence of distortion. This model has proven to be controversial and perhaps at least partly incorrect (Rancourt and Meunier, 2008), demonstrating how difficult it can be to determine definitively the structure of nanoparticles of interest to the soil community.

Another common application of XRD has been determination of particle size. Application of the Scherrer equation to observed peak (or line) broadening in XRD patterns been used to determine particle size for particles up to about 0.1 µm. However, the Scherrer equation often cannot be applied reliably to nanoparticles because of issues such as the fact that a large number of atoms in nanoparticles are associated with the surfaces of particles and aggregates, which limits translational symmetry (Hall et al., 2000). New approaches, for example, based on using the Fourier transform of a Debye-Scherrer diffraction pattern, can often provide information on average particle dimensions (Hall et al., 2000). The Fourier method can be used even when only a limited range of scattering angles has been measured. When details of particle size distributions rather than simply average particles size are needed, other techniques such as TEM imaging and small-angle x-ray scattering (Glatter and Krathy, 1982) can prove invaluable. PDF analysis applied to x-ray scattering results can be used to define particle size for nanoparticles of only a few nanometers in size, if shape effects are considered (Kodama et al., 2006). Michel et al. (2007b) found good agreement between results of PDF analysis and TEM-based measurements of particle size for different ferrihydrite samples. Nanoparticle aggregation is common and can complicate nanoparticle size determinations. In such cases, it can be useful to report both apparent individual particle size distributions and aggregate size distributions based on TEM observations.

Detecting and determining the structure and composition of nanoparticles adhered to the surfaces of larger minerals or rocks can be even more challenging. For example, Nugent et al. (1998) observed a patchy coating of nanoscale crystalline and amorphous aluminosilicate material on feldspar that had been naturally weathered in a spodosol. The coating was "largely undetected under scanning electron microscopy" but readily apparent in atomic force microscopy (AFM) images. Composition was determined from results of x-ray photoelectron spectroscopy (XPS), Auger electron spectroscopy (AEM), and secondary ion mass spectrometry (SIMS) analysis. Recently, Livi et al. (2009) characterized nanoscale mixed Ni-Al hydroxide surface precipitates on the clay mineral pyrophyllite using analytical electron microscopy, HRTEM, selected-area electron diffraction (SAED), powder XRD, and x-ray absorption fine structure (EXAFS) spectroscopy. The authors stressed the importance of applying such a combination of state-of-the-art techniques to analyze nanoscale surface precipitates.

3.2.2 Nanoparticle Surface Area

The world of nanoparticles is fundamentally a world of surfaces. Nanoparticles have extremely high specific surface areas for their volume and a significant proportion of atoms associated with nanoparticles occur at surfaces. For example, if we were to take a cube 1 mm on a side and divided it into cubes 1 nm on a side, the total volume would remain the same. But, the surface area would increase a million fold.

For a spherical particle, the ratio of surface area (in nm²; $A = 4\pi r^2$) to volume (in nm³; $V = 4/3\pi r^3$) is inversely proportional to the particle radius r (in nm) according to the simple relationship:

$$\frac{A}{V} = \frac{3}{r} \tag{3.1}$$

As a particle becomes smaller, its surface area becomes an increasingly larger component of its overall form or structure.

3.2.3 The Concept of Surface Free Energy

The significance of surface area in environmental systems is readily apparent from the simple experiment of pouring a little oil into water. The oil immediately balls up into spheres (or flattened spheres at the water surface). The hydrophobic oil is taking on the shape that minimizes the surface area in direct contact with water. This and other related commonplace observations suggest that surfaces must have some energy associated with them, known as the surface free energy (or, more correctly in many circumstances, the interfacial free energy). Surface free energy is a driving force for many physical or chemical transformations that act to minimize the surface free energy.

When new surface area is formed, the associated change in surface free energy must be considered in the overall energy change of the system. The (specific) surface or interfacial free energy (γ) is defined as

$$\gamma = \left(\frac{\delta G}{\delta A}\right)_{P,T}$$
 (pressure, temp., remain constant) (3.2)

where

G is the Gibbs free energy (in kJ) *A* is the surface area (in m²)

An interface will only be stable if the free energy of formation of the interface is positive; otherwise, the interface would eventually disappear. It should be noted that surface free energy refers to the *excess* free energy that molecules or atoms have by virtue of their being associated with a surface.

For a system that contains a surface, the total free energy of the system is the sum of the bulk free energy (G_{bulk}), which in turn is the sum of the molar free energies of formation of its constituents, i, $\Sigma_i \mu_i n_i$, where the chemical potential $\mu = (\delta G/\delta n_i)_{T,p}$, plus the total excess free energy of formation of all surfaces and interfaces j (G_s). The surface (or interfacial) free energy is given by $\Sigma_i \gamma_r A_i$. The total free energy (in kJ) is thus

$$G_{\text{tot}} = G_{\text{bulk}} + G_{s,j} \tag{3.3}$$

$$= \sum_{i} \mu_{i} n_{i} + \sum_{j} \gamma_{j} A_{j} \tag{3.4}$$

This concept of surface free energy has important implications for many environmental processes, especially those involving small particles with high specific surface area. A summarizing principle is that for small nanoparticles that have high specific surface area, anything that affects surface free energy can affect overall nanoparticle stability.

3.2.4 Surface Free Energy and Classical Mineral Nucleation Theory

Surface free energy plays an important role in mineral nucleation. Homogeneous nucleation of a new mineral phase from solution necessarily passes through a step in which a nanoparticle forms with very high specific surface area. The free energy of nucleation (G_n) of a crystal that forms from a supersaturated solution can be related to saturation state and surface free energy. The free energy of nucleation of a single crystal (ΔG_n) is the sum of the change in bulk free energy (ΔG_{bulk}) and the change in free energy that occurs upon formation of a new interface $(\Delta G_{\text{interf}})$ (Berner, 1980):

$$\Delta G_n = \Delta G_{\text{bulk}} + \Delta G_{\text{interf}} \tag{3.5}$$

where ΔG values are in kJ mol⁻¹. For a spherical particle,

$$\Delta G_n = -\left(\frac{4}{V}\right) \pi r^3 k_{\rm B} T \ln(\Omega) + 4\pi r^2 \gamma \tag{3.6}$$

where

V is the molecular volume of the precipitate (m³) r is the radius of the nucleus (m)

 $k_{\rm B}$ is Boltzmann's constant (1.3806 × 10⁻²⁶ kJ K⁻¹)

 Ω is the saturation ratio

T is the temperature (K)

 γ is the surface free energy per unit surface area of the nuclei (kJ $m^{-2})$

When the solution is supersaturated, $\Omega > 1$. ΔG_n has a maximum at the critical size of the nucleating crystal, which is designated r^* , or the critical nucleus. Once the critical nucleus is formed, any additional growth of the crystal results in a decrease in free energy and the overall process transitions from one of nucleation to growth. At any specific value of Ω , particles with $r > r^*$ will tend to grow and particles with $r < r^*$ will tend to dissolve. Greater Ω corresponds to smaller critical nucleus size, that is, smaller nuclei will be stable in more highly supersaturated solutions.

This element of classical nucleation theory has important implications for the mechanisms of mineral nucleation (Figure 3.6; Lower et al., 1998a, 1998b). At high supersaturation, we can expect that minerals will be likely to nucleate homogeneously in solution. But, at low supersaturation, such homogeneous nucleation is far less likely and heterogeneous nucleation on already existing surfaces (if such are available) is more favorable and thus more likely to occur. Soil environments, which tend not to be highly supersaturated with respect to many mineral phases, should not undergo much if any homogeneous nucleation directly from solution leading to crystal growth, although heterogeneous nucleation on the surfaces of already existing particles can occur more readily. An example of heterogeneous nucleation could potentially be formation of kaolinite as a secondary mineral precipitate on feldspar, although it should be emphasized that we do not fully understand the mechanisms of kaolinite secondary mineral formation in different environments.

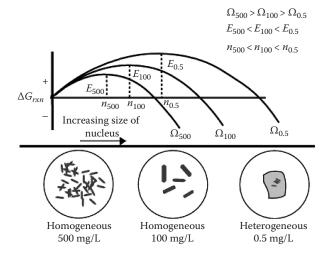

FIGURE 3.6 A schematic showing how saturation state affects nucleation of the Pb-phosphate mineral pyromorphite in the presence of apatite. Ω = saturation state E = activation energy at different saturation states, n = crystal size at different saturation states. From Lower et al. (1998b), after the general construct of Nielsen (1964).

3.2.5 Particle Size and Stability: Classical Theory

Related to this view of particle size and nucleation theory, we can consider how particle size affects stability. The high specific surface areas of small particles has always been taken to indicate that particles become less stable with decreasing size so that nanoparticles should, for the most part, be unstable. To understand the phenomenon of stability relationship to size, we can begin by considering how the pressure within a bubble changes with bubble size (or radius of curvature). According to the Young–Laplace equation, the pressure difference (ΔP) on either side of the surface of a thin film is related to the surface or interfacial tension (γ) and the radii of curvature (R_x , R_y , in m) of the surface:

$$\Delta P = \gamma \left(\frac{1}{R_x} + \frac{1}{R_y} \right) \tag{3.7}$$

For a spherical bubble, $R_x = R_y$, and the Young–Laplace equation reduces to

$$\Delta P = \frac{2\gamma}{R}.\tag{3.8}$$

Thus, the pressure inside a bubble becomes increasingly large as the bubble size decreases. Very small bubbles thus tend to be unstable, and initial bubble formation requires energy to overcome this free energy nucleation barrier.

Expanding this concept from gas bubbles in solution to more general interface phenomena, changes in particle stability with size are traditionally described by the modified Kelvin equation. This equation states that as a hypothetical particle gets smaller in size (r, in m) through the nanoscale range, its solubility (s) increases exponentially:

$$\frac{s(r)}{s_{\infty}} = \exp\left(\frac{2\gamma V_D}{rRT}\right) \tag{3.9}$$

where

 γ is the surface energy V_D is the molar volume of the disperse phase (m³) R is the ideal gas constant (8.314 J mol⁻¹ K⁻¹) T is the temperature (K)

The term s_{∞} refers to the solubility of a hypothetical particle with an infinite planar surface, that is, in the absence of curvature.

The marked decrease in stability with decreasing particle size can lead in some systems to evolution in particle size over time. Consider an aqueous system in which many small crystals have formed from a highly supersaturated solution. The numerous small crystals together have very high combined,

total surface area. This system of small, high specific surface area particles is thermodynamically unfavorable relative to a system with fewer large crystals and therefore lower interfacial free energy. Some of the small crystals will dissolve while others grow at their expense to larger dimensions. This spontaneous process of increase in average particle size over time is known as Ostwald ripening, named after Wilhelm Ostwald who first described the process in 1896. Because a system with many small particles has a larger overall surface area-to-volume (or mass) ratio than a system of few large particles, Ostwald ripening minimizes the total free energy of the system by decreasing surface (interfacial) energy.

The above discussion of classical theory suggests that nanoparticles in aqueous environments should be highly unstable and should eventually evolve into larger and more stable crystals. Yet, many nanoparticles can remain stable for long periods of time in aqueous suspensions or in porous media. As we shall see in the section below, particle size and stability can be related in a complex manner at the nanoscale, and classical theories do not always provide good explanations for observed phenomena.

3.2.6 Nanoparticle Stability: When More Than Size Alone Matters

Classical theories of crystal nucleation, growth, and stability as related to particle size withstood decades of inspection, helping to explain many important phenomena in the field and the laboratory. Within the last few years, however, nanoscience is demonstrating that the classical approaches do not always provide a clear understanding of phenomena involving minerals and other natural solids at the nanoscale. Conceptually, soil scientists recognize the general problem immediately: if small particles are inherently unstable, then why are soils, even paleosols, often dominated by mineral or amorphous solid particles less than 1 µm in diameter, including nanoparticles? Is it just that the kinetics of growth are very slow in low-temperature environments? Or, are there thermodynamic controls; that is, can nanoparticles be thermodynamically stable for reasons that we do not yet fully understand? These are questions that we do not yet have answers for in many systems. However, the work of researchers such as Navrotsky and her colleagues (Navrotsky, 2001, 2003; Navrotsky et al., 2008) is starting to suggest that both kinetics and thermodynamics can play a role in nanoparticle longevity in both the lab and the field.

In order to determine the controls on mineral nanoparticle stability as a function of size, one would ideally like to be able to grow nanoparticles of a given mineral phase in which only the size changes, but not the structure or composition. However, for many phases, it is impossible to change size, at least for the smallest nanoparticles, without also changing structure and/or hydration (Navrotsky et al., 2008). Among other factors, very small nanoparticles, in the 1–10 nm size range, have a high proportion of total atoms at or very near the surface. These atoms

experience different bonding environments than atoms of the same mineral in the bulk of a larger crystal. Thus, for very small mineral nanoparticles, the high proportion of surface and near-surface atoms can make it virtually impossible to change size independently of structure, and for many minerals, of composition. Moreover, very small nanoparticles of minerals such as hematite often are more hydrated than larger crystals, and this again affects stability (Navrotsky et al., 2008).

Difficulties associated with determining the structures of nanoparticles were discussed in Section 3.2.1. Beyond the overall structure of nanoparticles, we often cannot determine the surface structure and microtopography of mineral nanoparticles; yet, both of these characteristics affect surface free energy and crystal stability, especially within the nanoparticle size range. It can also be difficult to discern the ratios of different crystallographic faces exposed at the surfaces of nanoparticles. Given that different faces may have different structures, reactivities, and surface free energies, this further complicates our understanding of how stability changes as a function of nanoparticle size (A. Navrotsky, University of California at Davis, personal communication). Finally, impurities tend to accumulate at the surfaces of particles, and impurities can thus be expected to play a particularly important role in nanoparticle stability and reactivity (Waychunas et al., 2005).

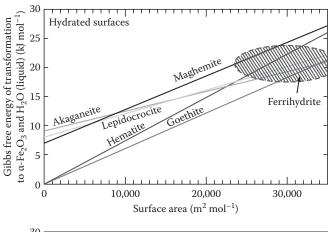

Recall from above that total free energy of a particle is equal to the sum of bulk free energy plus surface/interfacial free energy,

$$G_{\text{tot}} = \sum_{i} \mu_{i} n_{i} + \sum_{j} \gamma_{j} A_{j}$$
 (3.4)

The surface/interfacial free energy may become a major and potentially even dominant component of $G_{\rm tot}$ for nanoparticles, especially in the size range of only a few nanometers in diameter. This means that nanoparticle stability is not just a function of size, alone, but rather of complex structural, compositional, and microtopographic characteristics of the surface/interface.

Navrotsky's group has shown that the different polymorphs of the oxides of Al, Fe, Ti, and Zr can show varying degrees of stability at different particle sizes in the nanoscale versus micron scale (Navrotsky, 2001, 2003; Navrotsky et al., 2008), related to a large extent to differences in surface free energy. Phases that are metastable as micron-scale or "bulk" materials generally have larger surface energies than other polymorphs that are slightly metastable as bulk materials. Because of this competition between bulk metastability and surface energy, nanoparticulate oxides can exist as different stable polymorphs at different size ranges. This process can lead to crossovers in stabilities of different phases as a function of particle size.

Navrotsky et al. (2008) found that stability crossovers can be different for hydrated versus anhydrous surfaces of the Fe(hydr) oxide system. For example, particle size and hydration can play a key role in determining the relative stabilities of hematite and goethite of different nanoparticle sizes (Navrotsky et al., 2008). Surface enthalpy and free energy are generally much higher for anhydrous oxides such as hematite than for oxyhydroxides such as goethite. The lower surface enthalpy/energy for the hydroxide

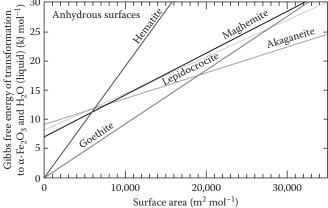

FIGURE 3.7 Enthalpy relative to coarse hematite $(\alpha - Fe_2O_3)$ plus liquid water as a function of surface area (corrected for compositional/structural differences in terms of Fe atoms). This figure illustrates the crossovers in stability at different surface areas (*note:* smaller particles tend to have higher surface area) and the differences between hydrated and anhydrous systems. (From Navrotsky, A., L. Mazeina, and J. Majzslan. 2008. Size-driven structural and thermodynamic complexity in iron oxides. Science 319:1635. With permission of AAAS.)

phase goethite allows this mineral to be stabilized relative to the oxide hematite at <~60 nm, corresponding to high surface area. Although micron-scale hematite particles in water tend to be more stable than goethite, the nanoparticle size range tends to favor goethite stability (Figure 3.7). The equilibrium relationships between hematite and goethite nanoparticles are sensitive to variations in other factors such as temperature, the activity of water, and Al substitution. Given that impurities tend to associate with surfaces, the high surface areas of nanoparticles may lead to the impurities being a significant proportion of the overall atoms associated with a nanoparticle, so that impurities can be expected to be particularly important to nanoparticle stability.

3.2.7 Stability and the Medium Surrounding a Nanoparticle

Another factor that can strongly impact nanoparticle stability in soils and other porous media is the solution composition, including pH, ionic strength, and concentrations of potential sorbates, in which nanoparticles are found. Because of the small size of nanoparticles and the high specific surface area, materials such as cations, anions, and organic molecules adsorbed to nanoparticles can become a major component of the overall nanoparticle structure and composition. This means that sorbed materials can affect nanoparticle stability, especially for nanoparticles less than a few nanometers in diameter. Because pH affects nanoparticle oxide surface site protonation, pH can affect stability through its effects on surface free energy, alone, beyond considerations of bulk saturation state.

3.2.8 A New Concept of Mineral Growth from Nanoparticles: Oriented Attachment

While Ostwald ripening appears to occur in many systems (Lower et al., 1998a, 1998b), minerals may grow from nanoparticulate nuclei by another mechanism known as oriented attachment. Oriented attachment as a mechanism for coarsening of nanoparticles has been demonstrated through the work of Banfield and her colleagues (Penn and Banfield, 1998a, 1998b). Oriented attachment is a process whereby adjacent nanoparticles spontaneously self-organize so that they share a common crystallographic orientation. The oriented particles are then joined along a planar interface, decreasing the overall surface area and surface free energy. Oriented attachment also can be a mechanism for dislocation generation in otherwise defect-free nanocrystals, when there is a small misorientation at the interface between the joining nanoparticles (Penn and Banfield, 1998b). Oriented attachment may also result in crystals that are separated by twin boundaries or other planar defects (Penn and Banfield, 1998b); the twin boundaries sometimes have atomic arrangements that are distinct from the crystal components on either side of the boundary (Figure 3.8; Penn and Banfield, 1998b). An important question is how prevalent oriented attachment is in actual field environments, including

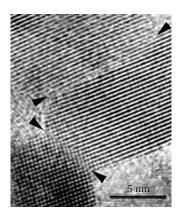

FIGURE 3.8 A high-resolution TEM (HRTEM) image of a particle that formed by oriented attachment of anatase (TiO_2). The original crystal boundaries remain as planar defects in the resulting particle. (From Penn, R.L., and J.F. Banfield. 1998b. Imperfect oriented attachment: Dislocation generation in defect-free nanocrystals. Science 281:969–971. With permission of AAAS.)

soils. The mechanism can only operate when the particles are free to move in order to align themselves, as in aqueous solutions, and could also potentially occur when nanoparticles nucleate next to each other on a solid substrate, through heterogeneous nucleation.

3.2.9 Nanoparticle Sorption, Redox Phenomena, and Catalysis

Because the basic properties of materials may be different at the nanoscale than at the bulk scale, and given the high surface areas of nanoparticles, an important question concerns the controls on sorption to nanoparticles and whether nanoparticles sorb ions and molecules differently than do larger, bulk materials. There are many different concepts and properties that must be considered in studies of these phenomena.

First, a few comments on "sorption" terminology are needed. The term "sorption" is used when the mechanism by which an adsorbate accumulates in association with a solid the adsorbent is unknown, or to refer to more than one process. Adsorption is the term of choice for a process in which individual species or small clusters accumulate in a two-dimensional fashion at an external surface. Absorption refers to accumulation that goes into a particle, such as into clay interlayers or micropores. Precipitation refers to a three-dimensional accumulation process associated with a surface, known as heterogeneous nucleation, or in the surrounding solution, known as homogeneous nucleation. Sorption phenomena often may play a role in redox reactions and catalysis (Huang, 1999).

Sorption is generally quantified in terms of moles (or grams) of sorbate per meter squared of sorbent surface area, with specific surface area generally measured by gas adsorption (or desorption) using the BET method (Brunauer et al., 1938). However, nanoparticles often aggregate during BET measurements, which can make it difficult to measure specific surface area reliably. Some nanomaterials may recrystallize, dehydrate, or otherwise change in shape and/or structure as a result of the temperature changes that occur during BET sample preparation and measurements, and this process needs to be considered in developing measurement protocols (Maurice et al., 2000).

Other techniques commonly used to characterize particles for use in sorption experiments also require special care when applied to nanoparticles. For example, measurements of electrophoretic mobility, or zeta potential, are often used to determine particle point of zero charge. Most commercial instruments apply the Smoluchowski equation for electrophoretic mobility, but this equation tends to break down for very small particles, and other approaches need to be considered (O'Brien and White, 1978; Maurice, 2009). Particle shape and suspension density can also be important, especially for nanoparticles, and particle aggregation is important because it can affect mobility.

Because the surface properties of nanoparticles change with particle size, we can expect sorption phenomena to be sensitive to particle size, as well. For example, titration experiments showed that the point of zero charge (pHzpc) of titania

nanoparticles changes with nanocrystalline size (Finnegan et al., 2007); differences in point of zero charge affect surface potential and can influence sorption behavior as a function of pH. Ha et al. (2009a, 2009b) investigated Zn(II) adsorption to hematite micron- versus nanoscale nanoparticles. They observed differences in adsorption complex structure and in formation of Zn-containing precipitates with hematite particle size.

Many particles in nature may have nanoscale porosity that can be very important for fate and transport of metals, radionuclides, and organic compounds. For example, the *d*-spacings of swelling clays such as montmorillonite, may swell to the nanometer scale, with thickness of the interlayer region itself approaching 1 nm. Sposito et al. (1999) showed that the structure of water in montmorillonite interlayers appears to be different from the structure of bulk water in solution. Hydrophobic organic compounds and organic cations may absorb in clay interlayers (Lagaly, 1981; Boyd et al., 2001; He et al., 2006) and the conformations of the absorbed organic molecules may be different from their conformations in bulk solution (Haack et al., 2008). Absorption into interlayers and nanopores can be important to contaminant fate and transport, and more research needs to be focused on the hydrology, hydraulics, structure of water, and reactivity of water and solutes in nanoscale spaces.

Because of growing concerns over greenhouse gas emissions and climate change, recent study is focusing on nanoscale sorption phenomena for CO2 capture. A current method for scrubbing CO₂ from power-plant emissions is the use of liquid amine as a solution absorbent. However, reversible capture by sorption on a solid phase could offer significant benefits. CO₂ may diffuse into the clay mineral pyrophyllite (Wang and Zhang, 2003) and sericite (fine-grained muscovite; Zhang et al., 2005) during dehydroxylation, but the potential extent of uptake and reversibility are not known. Fibrous clays such as palygorskite have channels that can take up water and SO₂ (Zhang et al., 2009); CO₂ uptake seems likely but is yet to be fully explored (R. Cygan, Sandia National Lab, personal communication, 2010). Zeolites and carbon molecular sieves can reversibly sorb significant quantities of CO₂ at room temperature, but they are less efficient at higher temperatures and have poor selectivity with respect to water (Zheng et al., 2005). Considering the success in using liquid amine for CO2 capture, research is focusing on aminemodified (nano)porous materials such as silica gels and polymers and mesoporous silica (Zheng et al., 2005).

For nanoparticles, size quantization of the electron structure, coupled with changes to surface structure and surface defect site density, may lead to different rates of electron transfer in redox reactions. Madden and Hochella (2005) showed that the rate of heterogeneous manganese oxidation by hematite nanoparticles is up to one and a half orders of magnitude greater for 7.3 nm average diameter particles than for 37 nm particles. This effect was apparent even when surface area was taken into consideration in the rate calculations.

Nanoparticles may have particularly useful catalytic properties because of the high surface areas they expose to the atmosphere or to solution and because of differences in surface

structure, electron transfer properties, and other characteristics. For example, ${\rm TiO_2}$ nanoparticles are widely used in photocatalysis applications (Aitken et al., 2006), and they have been shown to photocatalyze the degradation of pollutant organics (Armaleo et al., 2007). The heterogeneous Mn oxidation by hematite nanoparticles observed by Madden and Hochella (2005) is an example of a natural catalytic process. Nevertheless, although catalysis by nanoparticles is a topic of significant industrial research, far less is known about the potential catalytic properties of nanoparticles in nature.

3.3 Nanoparticle Mobility in Soils and Sediments

The small size of nanoparticles has important implications for their mobilities in porous media. According to Stokes' Law, particle settling velocity (v_s) (m s⁻¹) increases with the particle size (d_p) (m) and density (ρ_p) (kg m⁻³):

$$v_{\rm s} = \frac{g(\rho_{\rm p} - \rho_{\rm w})d_{\rm p}^{2}}{18\mu}$$
 (3.10)

where

g is the acceleration due to gravity (9.807 m s^-2) ρ_w is the density of water (kg m^-3) ρ_p is the particle density (kg m^-3) μ is the absolute viscosity of the water (Pa s or kg m^-1 s^-1)

Thus, when we consider nanoparticle mobility in porous media, it needs to be recognized that individual nanoparticles are subject to translational diffusion and Brownian motion, but that they are too small to be strongly affected by gravity.

DLVO theory, named after work by Derjaguin and Landau (1941) and Verwey and Overbeek (1948), has been widely used to help predict colloid stability as well as the sorption of colloids to sediment (i.e., collector) surfaces in porous media. In classical DLVO theory, the stability of particles in suspension is dependent upon total potential energy $V_{\rm T}$:

$$V_{\rm T} = V_{\rm A} + V_{\rm R} + V_{\rm S} \tag{3.11}$$

which is the sum of

 $V_{\rm A}$, potential energy due to attractive van der Waals forces

 $V_{\rm R}$, potential energy due to repulsive, electrical double layer, forces

V_s, potential energy due to the solvent, which is generally small and often neglected in the calculations

This classical DLVO theory has been expanded recently to include other forces of interaction such as Born repulsion and Lewis acidbase interaction (Grasso et al., 2002; Saiers and Ryan, 2005).

One of the challenges in dealing with nanoparticle aggregation and adsorption to surfaces of porous media is that classical and extended DLVO theories were developed for particles whose radius of curvature is greater than the thickness of the double layer, and this is often not the case for nanoparticles. Many interfacial forces, such as electrostatic and van der Waals, can extend over distances that are large in comparison with the size of an individual nanoparticle. Surface and interfacial forces that are not considered in classical DLVO theory, such as hydration/solvation and Born repulsion, are likely to be particularly important for interactions between nanoparticles or between a nanoparticle and a sediment particle (collector) surface (Maurice, 2009).

A great deal of recent research is focused on nanoparticle aggregation and how it affects mobility in porous media. Indeed, the two are linked because aggregated particles have been shown to transport differently than individual (colloidal) particles (Waite et al., 1991). Recently, Gilbert et al. (2007) investigated controls on aggregation of (highly disordered) goethite nanoparticles. Based on extensions to DLVO theory, particles of like charge should be unlikely to form stable aggregates because of repulsion between the like charges. However, aggregation can occur in solutions that have enough thermal energy to overcome this barrier to aggregation. Gilbert et al. (2007) observed the formation of nanoparticle aggregates or nanoclusters between pH 5 and 6.6, with diameters from 25 to ~1000 nm, which remained stable in suspension for at least 10 weeks. This formation of stable nanoclusters of an Fe(III)(hydr)oxide indicates that more attention needs to be paid to the role of nanoclusters in transport in porous media, especially given that many pollutants tend to adsorb to Fe(III)(hydr)oxide minerals.

A good deal of research is also focused on the suspension and aggregation of fullerenes in aqueous solutions. The fullerene C_{60} tends to be highly insoluble in water, but may be induced to form aqueous suspensions by prolonged stirring (Brant et al., 2005). Ma and Bouchard (2009) showed that suspended C_{60} nanoclusters form upon prolonged stirring can remain as stable aggregates in suspension for weeks or longer. The nanoclusters of C_{60} tend to exhibit pH-dependent surface charge, as measured by zeta potential. The mechanism whereby the surface charge is developed on the C_{60} nanoclusters in suspension is not yet understood (Ma and Bouchard, 2009). In any case, there is much that we presently do not know about fullerene surface properties,

charge, aggregation behavior, and potential transport through porous media, particularly under hydrologically unsaturated conditions and in long-term environmental exposure.

In hydrologically saturated porous media, it has been shown that colloids may be removed from the solution phase by sorption to the collector surfaces and/or pore straining, which is the trapping of particles in small pores. Many groups are investigating nanoparticle mobility in saturated porous media. Wang et al. (2008) investigated the retention and mobility of C_{60} aggregates in saturated columns packed with Ottawa sand and or glass beads. Retention of the aggregates was considerably greater in the presence of $1.0\,\mathrm{mM}$ CaCl₂ versus in deionized water without added electrolyte, due at least in part to electrostatic interactions.

In unsaturated conditions, as commonly encountered in soils, colloidal particles may be trapped by a thin film of water on collector surfaces, in a process known as film straining (Chen et al., 2008 and references therein). Colloids may also adhere to the air–water interface, and colloids can be found associated with bubble walls (Wan et al., 1994). Chen et al. (2008) observed that ${\rm TiO_2}$ nanoparticle mobility was affected by the saturated/unsaturated ratio in porous media and suggested that the nanoparticles may adsorb to the air–water interface.

Particle aggregation has been shown to play an important role in colloid mobility in porous media, and its effects on nanoparticle mobility are also being explored. Guzman et al. (2006) investigated the effects of pH on TiO₂ nanoparticle aggregation and transport in hydrologically saturated porous media consisting of two-dimensional microfluidic devices. They found that transport was influenced by both surface potential effects and size of nanoparticle aggregates. Nanoparticle aggregates could become clogged in pores (Figure 3.9). An important question raised was whether nanoparticle aggregates would behave similarly to colloidal particles and aggregates of colloids. For example, nanoparticle aggregates might potentially break apart or otherwise be altered by the presence of shear in flowing porous media.

Questions of natural and manufactured nanoparticle aggregation and transport in porous media are reviving interest in humic substances research. Humic substances are well known to affect colloid aggregation, fate, and transport, and are likely to

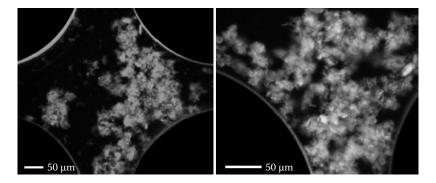

FIGURE 3.9 TiO_2 nanoparticle aggregates in microfluidic pore channels at pH 7. (With permission from Guzman, K.A.D., M.P. Finnegan, and J.F. Banfield. 2006. Influence of surface potential on aggregation and transport of titania nanoparticles. Environ. Sci. Technol. 40:7688–7693. Copyright 2006 American Chemical Society.) Important questions arise regarding the behavior of nanoparticle aggregates in porous media, such as whether new models need to be developed and how aggregates will behave in response to shear forces.

be equally or even more important for nanoparticles. Chen and Elimelech (2008) investigated C_{60} deposition kinetics onto bare silica surfaces or surfaces precoated with natural organic matter (NOM) in the form of humic acid (Figure 3.10) or alginate. They observed that preadsorbed NOM on the silica surface can either retard or enhance the deposition kinetics, depending on the solution ionic composition and the physicochemical properties of the NOM. On the other hand, the presence of NOM in solution tended to decrease deposition, which the authors attributed to steric repulsion upon NOM sorption. This suggests that the effects of NOM, including humic substances, can be complex and different in diverse environments such as soils, groundwaters, or colloid-containing surface waters.

Interaction of fullerene (C-60) nanoparticles with humic acid and alginate coated silica surfaces: Measurements, mechanisms, and environmental implications. Environ. Sci. Technol. 42:7607–7614. Copyright 2008 American Chemical Society.)

3.4 Nanotoxicity

Many engineered nanoparticles have the potential to be toxic to humans and/or ecosystem components such as microorganisms, plants, aquatic, and other organisms (NRC, 2008; Wiesner et al., 2008). A recent report from the National Research Council (NRC, 2008) stressed the pressing need for a national strategy for nanorisk research to evaluate the environmental health risks of nanotechnologies and engineered nanoparticles. The field of nanotoxicology is one of the new disciplines that has emerged over the last decade as an outgrowth of the explosion of research and development in nanoscience and nanotechnology. As pointed out by Oberdorster et al. (2005), the small size of nanoparticles makes it much easier for them to penetrate pores in skin, to be integrated into the respiratory system, and to penetrate cells. The high surface areas of nanoparticles can make them far more bioreactive. Thus, there is much real concern about nanotoxicity, especially given that so many new engineered nanoparticles are being released to the environment without toxicology analysis.

In some instances, the toxicity of nanoparticles is being touted for its potential health benefits, for example, as microbicide agents. Sondi and Salopek-Sondi (2004) showed that Ag nanoparticles have strong antimicrobial effects against *Escherichia coli*. Electron microscopy revealed clear cell damage, including pits in the cell walls and Ag nanoparticle accumulation in the microbial membrane (Figure 3.11). Results such as these are leading to widespread use of Ag nanoparticles as antimicrobial agents in detergents, on clothing, and in other applications.

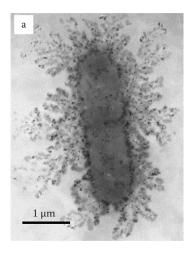

FIGURE 3.11 Silver (Ag) nanoparticles have toxic effects on *E. coli*. A TEM image of *E. coli* following exposure to Ag nanoparticles for 1 h. (With permission from Sondi, I., and B. Salopek-Sondi. 2004. Silver nanoparticles as antimicrobial agent: A case study on E-coli as a model for Gram-negative bacteria. J. Colloid Interface Sci. 275:177–182. Copyright 2004 American Chemical Society.) Some particles have penetrated into the cell. Intracellular materials have leaked into the medium surrounding the cell and Ag nanoparticles are attached to this material. This nanoparticle toxicity is leading to the use of Ag nanoparticles as antimicrobial agents in many products from detergents to dissemination on clothing.

Nanotoxicity to plants, or nanophytotoxicity, is another area of growing research. Lin and Xing (2008) found that ZnO nanoparticles had a (phyto)toxic effect on Ryegrass (*Lolium perenne*). The ZnO particles adsorbed into root tissues and cells and damaged the root tissues, inhibiting seedling growth. The phytotoxicity could not be explained by dissolution of ZnO particles, and dissolved Zn, but rather appeared to result from the actual nanoparticles themselves.

3.5 Nanoenabled Sensing

The revolution in nanotechnology promises to have another major impact on soil science in the form of nanoenabled sensing. There are many nanodevices that can be used for in situ sensing of soil components. Lee et al. (2008) developed colorimetric uranium sensors based on a uranyl (UO₂²⁺)-specific DNAzyme and gold nanoparticles (AuNP). A DNAzyme is essentially a DNA molecule that changes its fluorescence properties upon sorption of a specific component such as uranyl. In the nanosensor approach, uranyl-specific DNAzyme was attached to AuNP, forming functionalized purple aggregates. Uranyl-induced disassembly of the functionalized AuNP aggregates, resulting in individual AuNPs that were red in color. This nanosensor system was shown to have a detection limit of 50 nM uranyl.

Many other groups are using nanotechnology to develop sensors, or sensors that are approaching the nanoscale, specifically for soil applications. Bendikov et al. (2005) developed flexible, miniature, and inexpensive nitrate sensors that are fabricated by electropolymerizing pyrrole onto carbon fiber substrates using nitrate as a dopant. The resulting sensor shown in Figure 3.12 (length 1 cm or less, micron-scale diameter) is ideal for deployment in the pore space of soils and sediments and can quantify nitrate concentrations to just below 10⁻⁴M. Although this

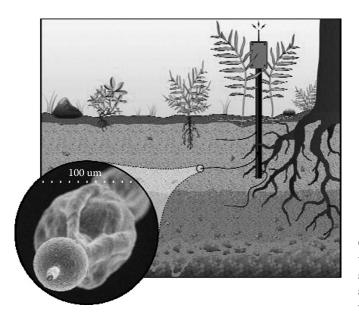

FIGURE 3.12 A soil nitrate microsensor as described by Bendikov et al. (2005). (Courtesy of T. Harmon and U.C. Merced.)

sensor is not nanoscale per se, it demonstrates the trend in miniaturization that is occurring in environmental sensors for soil applications.

3.6 Frontiers in Research in Nanoscale Particles and Processes in Soil Environments

Soil science is very much at the center of nanoscience and nanotechnology. On the one hand, soils are replete with natural nanoparticles and soil scientists have a long and distinguished history of investigating small particles in nature. On the other hand, nanoengineering is resulting in the release of an enormous number and diversity of nanoparticles to the environment, and they are certain to find their way into soils. Nanotechnology also is contributing to a new generation of sensors that can be used to investigate a host of soil parameters and processes.

Some frontiers for research involving soil science and the nanoscale include the following:

- 1. What are the unique properties of water in nanopores?
- 2. What are the controls on nanoparticle aggregation kinetics, and how do soil components such as NOM, monoand multi-valent ions, and bacteria affect aggregation of natural and engineered nanoparticles?
- 3. What are the controls on nanoparticle mobility not only in the saturated zone but also in hydrologically unsaturated environments?
- 4. What are the fundamental controls on nanotoxicity, and how can we prevent potentially toxic engineered nanoparticles from entering the food supply?
- 5. How well does our new primarily laboratory-based understanding of nanoparticles and nanoprocesses translate to real-world environments, including soils?
- 6. What implications will our ability to detect and study nanoparticles in soils and water have for various nations' regulatory structures related to pollutants?
- 7. How can nanotechnology best be used in soil science and broader agricultural applications, from sensing to treatment of crop diseases to controls on soil porosity, structure, and fertility?
- 8. How can we best harvest the strengths of nanoscience and nanotechnology while at the same time minimizing the risks to environmental and human health?
- 9. How can the unique abilities and perspectives of soil scientists be harnessed to contribute most successfully to the broader nanoscience and nanotechnology communities?

Given the unique properties and behaviors of nanoparticles, and the burgeoning of nano research and development, it is impossible to predict the potential long-term costs and benefits to soils and agriculture. One certain fact is that the soil community, with its long history of dealing with complex systems of small particles, has a great deal to contribute to understanding complex environmental processes at the nanoscale.

4.1 Introduction

4.1.1 Chapter Objectives, Terminology, and Definitions

This chapter seeks to provide some answers to questions about the role of nanoparticles (NPs) in controlling or influencing single and/or coupled chemical, biological, and hydrological processes in terrestrial ecosystems with various physical and mineralogical properties. This is a new and active area of research. For this reason, book chapters or review papers can quickly become outdated. In addition, many topics within this area of research have been explored only superficially, making the writing of critical analyses and comprehensive syntheses on specific or more general topics difficult. Under these circumstances, the aim of this chapter is to present recent results that have contributed to the current understanding of the impact of environmental NPs (ENPs) on these processes. Several important aspects of soil/geo nanoscience as we currently understand it are explained; and then ideas for future efforts and a direction for research in this fascinating, ever-expanding, and quickly advancing area within the soil and geosciences domains are presented. Additional information on NPs' unique properties and behavior and insights on how nanoscience is changing our views in many directions are provided in Chapter 3 (Maurice, 2012).

NPs are defined as particles with at least one of the three dimensions in the range from 1 nm to tens of nanometers (Hochella et al., 2008). These natural NPs (NNPs) are ubiquitous in terrestrial ecosystems and have been present for many years. However, it is very likely that in the near future the NP population (in terms of types and concentration) in soils will grow considerably and even unconventionally, that is, with not easily determined trends, when manufactured NPs (MNPs), which are engineered for different purposes in many areas of human activities, will enter the terrestrial ecosystems and become ENPs. The focus of this chapter is only on ENPs that are present in terrestrial systems and not on those in other environmental media, such as atmosphere or hydrosphere.

Within the context of this chapter, terrestrial ecosystems (e.g., soils, subsoils, deep vadose zone, and unconsolidated aquifer materials) are considered those that are present in the thin layer of the Earth's crust from the surface down to subsurface groundwater. Chemical, biological, and hydrological soil- or geo-processes are those that, directly or indirectly, control or influence the extent and timescale of the mobility and, in some cases, determine the ultimate fate of aqueous or sorbed

(adsorbed or precipitated) chemical species of naturally occurring or anthropogenic nutrients and contaminants, in terrestrial ecosystems with different physical and mineralogical properties. These processes may alter the soil mineralogy, change the particle size distribution or the surface and/or internal morphological features of soil minerals (e.g., mineral dissolution followed by neophase precipitation), modify surface chemical properties of the soil/sediment matrix (e.g., adsorption and desorption), or manipulate the chemical speciation (e.g., concentration gradients) and valence state (e.g., oxidation and reduction) of nutrients or contaminants.

4.1.2 Size-Dependent Properties: What Is Unique about NPs

The idea of crystallite size-dependent properties has circulated in the literature for quite some time (Gravie, 1978), and a great deal of time and effort has been spent over the past few decades to understand the properties and behavior of different size fractions that are present in terrestrial systems. These include colloidal fractions, clay fractions, silt fractions, sand fractions, and gravel. Each size fraction has specific properties and roles within the soil/sediment matrix. For this reason, the nanofraction, which is a subset of the soil colloidal fraction, should not be excluded from this rule. However, unlike other soil particles, many aspects of NPs have been little studied (Waychunas and Zhang, 2008), and our understanding of nanomaterials (particles, films, and/or confined fluids) is far from being complete from a fundamental physical chemistry point of view (Hochella, 2007). Recently, research efforts have intensified in this field because of the significant increase in the production of MNPs (Seeger et al., 2009), which almost certainly will find their way to terrestrial systems in substantial amounts and are expected to affect significantly naturally occurring soil- and geo-processes.

The smallest size fraction (fine-grained, submicro, or ultrafine fraction) has always attracted the attention of the soil scientists because of its unique properties, such as the large surface area, the large percentage of surface atoms with unbalanced charge, and the large number of surface functional groups per unit of mass. The smallest size fraction has the ability to dramatically change the soil physical and chemical properties, such as soil water holding capacity, tortuosity, particle aggregation, cation exchange capacity (CEC), anion exchange capacity (AEC), and so on.

It is also true that soil scientists have carefully studied the properties of clay and colloidal fractions in soils for years. However, attention has only recently been drawn toward the nanofraction, and legitimate questions have been raised: Do NP-specific, chemical, physical, and geological properties really exist? How do the properties and behaviors of NPs differ from those of ions and molecules and from those of the larger particles whose properties are understood based on classic physics and chemistry of bulk systems (Maurice and Hochella, 2008)? What is the role of the nanosize fraction in soils, and how does this fraction control or affect the extent and timescales of chemical, biological, and hydrological processes in soils?

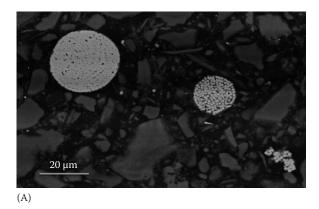

The general belief is that NPs can have unique size-related composition, stability, chemical reactivity, molecular and electronic structure, and mechanical behavior (Hochella, 2002; Kahru et al., 2008; Maurice and Hochella, 2008; Waychunas and Zhang, 2008). Especially important are those properties that emerge only after a cluster of atoms has grown beyond some specific size and that disappear once the particle grows beyond the NP range (Banfield and Zhang, 2001). NP properties are often different (sometimes dramatically different) from those of the same material at a larger size and could even show marked departures from their bulk analog materials (Hochella, 2008; Waychunas and Zhang, 2008). In addition, NPs may contain unusual forms of structural disorder that can substantially modify the properties of the materials and, therefore, cannot be considered as small pieces of the bulk material (Gilbert et al., 2004, 2006a). Interestingly, in some cases, for example, ferrihydrite, larger than the nanoscale equivalents, does not even exist (Hochella, 2008).

Considering that for particles on the order of 4 nm in diameter, ca. 50% of the atoms are at the surface, understanding the surface properties and surface chemistry of NPs is essential to fully understand their behavior (Grassian, 2008). Recent investigations have also demonstrated that the electronic and structural properties (Luca, 2009), magnetic properties (Carta et al., 2009), elasticity and compressibility (Gilbert et al., 2006a; Chen et al., 2009a), point of zero charge (PZC) (Vayssieres, 2009), surface free energy (Naicker et al., 2005; Zhang et al., 2009), and melting behavior (Qi et al., 2001) change significantly even within the NP size fraction.

4.1.3 Occurrence and Origin of NPs in Terrestrial Ecosystems

4.1.3.1 Natural NPs

Volcanic dust, most natural waters, soils, and sediments are sources of NNPs, which are generated by a wide variety of soil, geological, and biological processes (Handy et al., 2008a). Natural, accidental, and incidental nanomaterials such as fullerenes have existed on Earth for nearly 2 billion years and are common constituents in combustion exhaust (Posner, 2009). In terrestrial systems, NPs occur as nanominerals [which are defined as minerals that only exist in this size range, for example, certain clays and Fe and Mn (oxyhydr)oxides] (Hochella et al., 2008) or mineral NPs (which are defined as minerals that can also exist in larger sizes, e.g., most known minerals) (Hochella et al., 2008). NPs are widespread components of soils, ranging from the nanomineral ferrihydrite, to a wide variety of mineral NPs, to nanoscale aggregates of natural organic matter (NOM), and to bacterial appendages known as nanowires (Maurice and Hochella, 2008). Soils contain many kinds of inorganic and organic particles, such as clay minerals, metal (hydr) oxides, and humic substances, whereas allophane and imogolite are abundant in volcanic soils (Theng and Yuan, 2008). Nanoparticulate goethite, akaganeite, hematite, ferrihydrite, and schwertmannite are important constituents of soils and

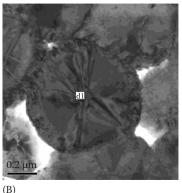

FIGURE 4.1 (A) Framboidal pyrite from a naturally bioreduced alluvial sediment from Rifle, CO. (B) High magnification image of a fibbed section of framboidal microcrystal (nanorim [<100 nm] with a chemical composition that is different from that of the bulk microcrystal). (Taken from Qafoku, N.P., R. Kukkadapu, J.P. McKinley, B.W. Arey, S.D. Kelly, C.T. Resch, and P.E. Long. 2009. Uranium in framboidal pyrite from a naturally bioreduced alluvial sediment. Environ. Sci. Technol. 43:8528–8534. Copyright 2009 American Chemical Society.)

sediments (Waychunas et al., 2005). The soil humic substance consists of a mixture of identifiable nanoscale biopolymers obtained, for example, directly from plant tissues that are added annually by maize plant residues (Adani et al., 2009). Within the soil profile, NPs that are formed during weathering of the primary minerals in the surface horizons where the chemical and biological processes are more intense may be transported downward to deeper horizons or groundwater by advective flow.

Based on a morphological criterion, NPs are classified into three categories: nanofilms (or nanosheets), nanorods, and NPs (Hochella et al, 2008). Nanosheets or thin surface coatings usually cover surfaces of primary minerals partially or fully, or they are products of the weathering processes that accumulate on the soil mineral surfaces, such as, for example, those on the surfaces of the microcrystals of framboidal pyrite found in a naturally bioreduced subsoil from Rifle, CO (Figure 4.1) (Qafoku et al., 2009). Typically, coatings consist of either pure or mixed forms of oxides and oxyhydroxides of Fe or other elements. However, they may also have a remarkably diverse composition (Penn et al., 2001). For example, the yellowish red to strong brown coatings on sediments from an Atlantic coastal plain aquifer in Virginia were predominantly a mixture of Si- and Al-rich nanophases of variable crystallinity with interspersed smectite and agglomerates of goethite NPs (Penn et al., 2001). In addition, clusters of bacterial cells, diatom fossils, sponge spicules, and other trace minerals were also observed during this investigation.

Examples of goethite nanoneedles and sodalite nanorods formed in the Hanford, WA, subsoil are presented in Figures 4.2A and 4.3B and C. NPs of hematite are presented in Figure 4.2B. NPs of ferrihydrite, which is a common soil mineral, are presented in Figures 4.4 and 4.5 (Hochella et al., 2005). In addition, examples of the chemical structure of nanotube imogolite and nanoball allophane, which are two naturally occurring nanoscale aluminosilicate minerals, are presented in Figure 4.6 (Abidin et al., 2007a, 2007b).

A special group of NNPs is formed in terrestrial ecosystems as a result of human activities causing unintentional accelerated

weathering of primary soil minerals and formation of secondary minerals. In some terrestrial environments, NPs are formed when soil (or subsurface sediment) is exposed to extreme conditions, which promote accelerated and intensive dissolution of existing minerals and subsequent precipitation of nanoscale neophases (Figures 4.2 and 4.3). One example is the sediment beneath the tank waste farms at the Hanford site, WA, which was exposed to leaking fluids from the waste tanks, creating unusually extreme conditions of high alkalinity (pH ~ 14) and extreme salinity (~1 M NaNO₃). As a result, intense dissolution of the soil minerals occurred followed by precipitation of hematite and goethite NPs (Figure 4.2) and feldspathoids in the group of cancrinite and sodalite (Figure 4.3) (Qafoku et al., 2003a, 2003c, 2004a, 2007b; Zhao et al., 2004; Mashal et al., 2005). These chemical and mineralogical transformations significantly affected the mobility of different contaminants present in the waste liquids (Chorover et al., 2003; Qafoku et al., 2003b, 2007a).

Another group of NNPs is formed via biotic processes, for example, biogenic uraninite (UO₂) (Singer et al., 2009) (Figure 4.7). This formation pathway was demonstrated in experiments involving the synthesis of biogenic UO₂. This was accomplished by reduction of aqueous uranyl ions by Shewanella putrefaciens CN32 (Singer et al., 2009). The fresh nanoscale UO₂ produced by Shewanella oneidensis strain MR-1 was found to exhibit a wellordered interior core of diameter ca. 1.3 nm and an outer region of thickness ca. ~0.6 nm in which the structure was locally distorted (Schofield et al., 2008). No evidence for lattice strain of the biogenic uraninite NPs was found in this study. The lack of NP strain and structural homology with stoichiometric UO₂ suggests that established thermodynamic parameters for the latter material are an appropriate starting point to model the behavior of nanobiogenic UO₂ (Schofield et al., 2008). Results from another team of researchers showed two distinct types of prokaryotic cells (inferred to be sulfate-reducing bacteria) that precipitated only a U(IV) mineral uraninite (UO₂) or both uraninite and metal sulfides, in a U-contaminated sediment from an inactive U mine anaerobically incubated with organic substrates (Suzuki et al., 2003).

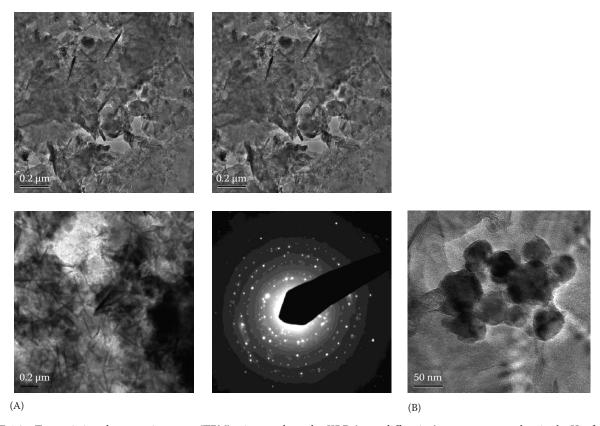

FIGURE 4.2 Transmission electron microscopy (TEM) micrographs and μ -XRD (x-ray diffraction) measurements taken in the Hanford sediments treated with high alkaline and saline solution. (A) Needle-like goethite NPs are shown in these micrographs, while the μ -XRD depicts the crystalline nature of these solids. (B) Hexagonal crystals of hematite NPs. (Taken from Qafoku, N.P., O. Qafoku, C.C. Ainsworth, A. Dohnalkova, and S.G. McKinley. 2007b. Fe-solid phase transformations under highly basic conditions. Appl. Geochem. 22:2054–2064. Copyright 2007, with permission from Elsevier.)

Biological processes may also lead to the formation of minerals via, for example, biologically induced oxidation of Fe(II) by anaerobic Fe-oxidizing bacteria. Fe biomineralization by the anaerobic nitrate-dependent Fe-oxidizing bacterium *Acidovorax* sp. strain BoFeNI in the presence of dissolved Fe(II) was recently studied, and all detected minerals consisted mainly of amorphous Fe phosphates (Miot et al., 2009).

4.1.3.2 Manufactured NPs

The majority of nanotechnologies are, according to one researcher, simply MNP production (Posner, 2009). They are producing and will continue to produce numerous MNPs in the coming years (Johansen et al., 2008). Hundreds of commercial products containing MNPs are used in many areas of human activities. For example, cerium dioxide NPs (CeO₂) are used as a catalyst in the automotive industry (Hoecke et al., 2009); Ag NPs are integrated into consumer and medical products (Bradford et al., 2009); ZnO NPs are used in solar cell device as the photoelectrode (Chen et al., 2009b); TiO₂ NPs are used in cosmetics, sunscreens, paints, and coatings, in addition to photocatalytic degradation of various pollutants in water, air, and soil matrices (Higarashi and Jardim, 2002; Nagaveni et al., 2004; Aarthi et al., 2007; Aarthi and Madras, 2008; Fang et al., 2009). Another group of MNPs (often called functionalized NPs) is used for decontamination purposes,

that is, contaminant immobilization (Mattigod et al., 2005). An overview of the classes of NPs relevant to the environment, a comparison of the MNP with NNP and a summary of their formation, emission, occurrence, and fate in the environment is presented in the following reference (Nowack and Bucheli, 2007).

A recent study has confirmed that MNPs are present in the environment (Kaegi et al., 2008). Direct evidence of the release of TiO₂ NPs, with a size of about 20-300 nm (used in large quantities in exterior paints as whitening pigments) from exterior facade paints to the discharge into surface waters, was presented in this study. Analytical electron microscopy and bulk chemical analysis revealed that TiO2 particles were detached from new and aged facade paints under the effect of natural weather conditions, then were transported by facade runoff and subsequently were discharged into natural, receiving waters. Apparently, this is the first report to present data on the calculated number densities of synthetic TiO2 particles in the runoff. This and other studies (Kaegi et al., 2008; Mueller and Nowack, 2008; Koelmans et al., 2009) have raised the discussion about ENP to a more quantitative level. Our knowledge on this subject is increasing almost exponentially because of increasing interest and increased funding, although many investigations still have explorative character and raise more new questions (Nowack, 2009b) than provide answers to the "old" ones.

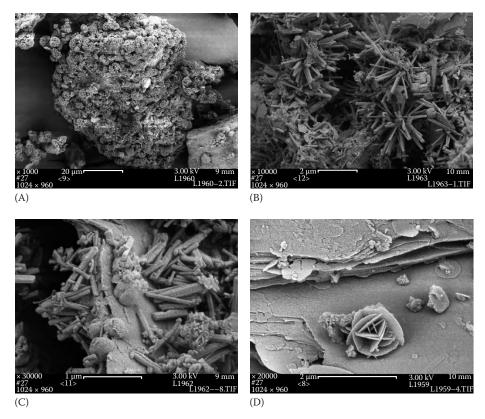

FIGURE 4.3 Sodalite $[Na_4Al_3(SiO_4)_3NO_3]$ nanorods and cancrinite $[Na_6Ca_2Al_6Si_6O_{24}(CO_3)_2]$ NPs formed when the subsoil minerals were exposed to extreme alkaline and saline conditions. Copyright 2010, with permission from Elsevier.)

4.1.4 ENP Toxicity

The field of nanotoxicology, which is a branch of bionanoscience, has become extensive and controversial over the last few years. Although a few years ago data on the potential environmental effects of NPs were scarce (Kahru et al., 2008) and limited information was available on the environmental behavior and associated potential risks of MNPs (Wang et al., 2009), an increasing body of information on this subject is now available in the literature. However, this topic is not discussed in detail in this chapter. For an in-depth coverage of different aspects of nanotoxicology, the reader is referred to the following references: Guzman et al. (2006a), Cañas et al. (2008), Handy et al. (2008a, 2008b), Johansen et al. (2008), Ju-Nam and Lead (2008), Kahru et al. (2008), Lee et al. (2008), Mueller and Nowack (2008), Navarro et al. (2008a, 2008b), Bradford et al. (2009), Drobne et al. (2009), Farre et al. (2009), Hull et al. (2009), Koelmans et al. (2009), Posner (2009), Wang et al. (2009), Zhang and Chen (2009), and Qafoku (2010).

4.2 Interactions in the Binary System: Nanoparticles–Soil Solution

In order to better understand the behavior of ENPs in terrestrial systems, it is essential to initially understand their interactions with different components of natural waters, including dissolved NOM, over a broad range of physicochemical conditions (Ju-Nam and Lead, 2008; Domingos et al., 2009). For this reason, the discussion in this section is focused on the behavior and reactivity of NPs exposed to different conditions of the soil aqueous phase. The binary interaction between NPs and the soil solution is presented and discussed in terms of NP formation, stability and aggregation, and their ability to serve as adsorbents, surface-mediated precipitation catalysts, or electron donors and acceptors. The extent and timescales of these processes depend on geochemical variables such as pH, OM content, and dissolved OM (DOM) concentration and on properties such as NP size, shape, concentration (Akbulut et al., 2007; Hoecke et al., 2009), type, age, and the presence of surface impurities.

4.2.1 Nanoparticle Formation and Stability

4.2.1.1 Formation

Crystals usually grow by attaching ions to inorganic surfaces or organic templates (Banfield et al., 2000). An alternative nucleation and crystal growth mechanism for NPs, namely, the oriented aggregation mechanism, is important coarsening process under a wide range of conditions encountered in the laboratory and in natural environments (Penn and Banfield, 1999). The oriented aggregation is defined as the irreversible and

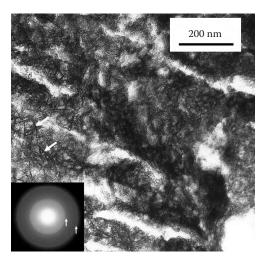

FIGURE 4.4 Transmission electron microscopy (TEM) image of six-line ferrihydrite with a small amount of vernadite-like mineral (dark, fiber-like particles, two of which are indicated by white arrows in the image) from the riverbed at Miles Crossing. The selected-area diffraction pattern of the ferrihydrite shows the broad, very weak lines from this mineral. The inner and outer arrows indicate the positions of the 2.57 and 1.49 Å lines, respectively. The 2.20 and 1.70 Å lines are barely visible between these two and are most easily seen on the left side of center. (Taken from Hochella, M.F., T. Kasama, A. Putnis, C.V. Putnis, and J.N. Moore. 2005. Environmentally important, poorly crystalline Fe/Mn hydrous oxides: Ferrihydrite and a possibly new vernadite-like mineral from the Clark Fork River Superfund Complex. Am. Mineral. 90:718–724. With permission from Mineralogical Society of America.)

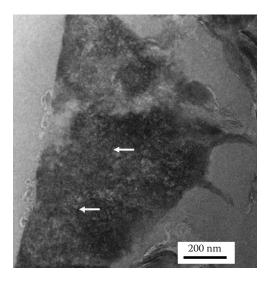

FIGURE 4.5 Transmission electron microscopy (TEM) image of a two-line ferrihydrite with a small amount of a vernadite-like mineral from the upper level of the floodplain of Kohr's Bend, collected at a depth of 15 cm. The arrows point to rare fiber-like features in this image. (Taken from Hochella, M.F., T. Kasama, A. Putnis, C.V. Putnis, and J.N. Moore. 2005. Environmentally important, poorly crystalline Fe/Mn hydrous oxides: Ferrihydrite and a possibly new vernadite-like mineral from the Clark Fork River Superfund Complex. Am. Mineral. 90:718–724. With permission from Mineralogical Society of America)

Henmi. 2007a. Differential formation of allophane and imogolite: Experimental and molecular orbital study. J. Comput. Aided Mater. Des. 14:5–18.)

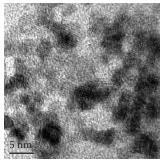

FIGURE 4.7 Images of biogenic uraninite UO₂ NPs, a product of microbial U(VI) reduction by a soil bacterium *Shewanella* sp. (Courtesy of Alice Dohnalkova, EMSL, Pacific Northwest National Laboratory, Richland, WA.)

crystallographically specific self-assembly of primary NPs and results in the formation of new single crystals, twins, and intergrowths (Penn et al., 2007). The oriented aggregation has been established as an important nonclassical crystal growth mechanism by which nanocrystals grow, unique and asymmetric morphologies are produced, and defects are incorporated into initially defect-free nanocrystals (Penn et al., 2006). Molecular dynamics simulations demonstrate that lowering of NP energy by changing orientation may drive crystal growth via oriented aggregation (Spagnoli et al., 2008).

A high-resolution transmission electron microscopy and low-temperature magnetometry study of synthetic goethite nanocrystals showed that nanocrystals grow almost exclusively by oriented aggregation of $3-4\,\mathrm{nm}$ primary nanocrystals (Guyodo et al., 2003). In another study, however, three coarsening mechanisms were found for anatase depending on solution pH (Finnegan et al., 2008): Ostwald ripening (pH > 11), oriented attachment and Ostwald ripening (pH = 2–11), and oriented attachment growth, followed by anatase dissolution and subsequent rutile formation (pH < 2).

Researchers also believe that to understand how dislocations, which are common defects in solids, are formed during early growth is of fundamental importance to understanding crystal growth (Penn and Banfield, 1998b). Dislocations are created when nanocrystalline materials grow by oriented attachment at crystallographically specific surfaces and there is a small misorientation at the interface (Penn and Banfield, 1998b). Twinning and polytypism in macroscopic crystals can originate at oriented interfaces between primary nanocrystalline particles early in their crystallization history (Penn and Banfield, 1998a). Maghemite (γ -Fe₂O₃)-like surface defects, for example, were found on the hematite (α -Fe₂O₃) NP with sizes of 7, 18, 39, and 120 nm (Chernyshova et al., 2007).

A variety of variables, such as soil solution pH (Myers and Penn, 2007; Finnegan et al., 2008; Isley and Penn, 2008), OM content, and DOM concentration (Eusterhues et al., 2008) in addition to a multitude of NP properties, such as type, size (Penn et al., 2006; Chernyshova et al., 2007), concentration, age, aggregation, size, and formation pathway (biotic or abiotic), may affect (i) the NP crystal structure formation and coarsening and (ii) the kinetics of phase formation and phase transformation. Even surface impurities may inhibit NP growth and phase transformation when they exist as surface clusters (Chen et al., 2007).

NP growth and phase transformation may also be time dependent. Growth by oriented aggregation was found to be consistent with the second-order kinetics with respect to the concentration of the primary NPs (Penn et al., 2007). These researchers also found that the overall rate constant for growth by oriented aggregation increased dramatically with decreasing primary particle size, which explains the common observation that growth by oriented aggregation slows as a function of continued crystal growth. Other investigators have found that the NP aggregation state has a marked influence on the kinetics of phase transformation and particle coarsening of three nanophases of titania (anatase, brookite, and rutile), probably due to the lowering of NP surface energy by interparticle interactions (Zhang and Banfield, 2007).

4.2.1.2 Stability

The stability of NPs is a function of their surface energy, and NPs are more stable when they possess a low surface energy. For example, the surface energies of small rutile particles are higher than those for anatase particles of a similar size, consistent with anatase being the more stable phase of nanocrystalline TiO₂ (Naicker et al., 2005). The surface free energy of NPs in an aqueous solution consists of the electrostatic energy of charged surfaces and interfacial energy (Finnegan et al., 2007). Both these terms can be modified by solution chemistry. They can also be manipulated to control NP phase stability and transformation kinetics (Finnegan et al., 2007). In addition, a better understanding of the stability of nanostructures in different chemical environments can be achieved by the incorporation of a size-, shape-, and temperature-dependent thermodynamic model, into theoretical descriptions of nanomaterials (Barnard and Xu, 2008).

Recently measured thermodynamic data on formation and surface energies of Fe oxides, which occur in almost all terrestrial ecosystems and exist in a rich variety of structures and hydration states, have been presented in a recent publication (Navrotsky et al., 2008). These authors studied the size-driven crossovers in stability, and they claim that this would help to explain patterns of occurrence of different Fe oxides in nature.

A kinetic equation that incorporates the dependence of the rate constant on the particle size for phase transformation via interface nucleation in NPs is proposed (Zhang and Banfield, 2005). These authors found that the temperature dependence of the rate constant of a kinetically controlled phase transformation could be usually described by the Arrhenius equation, which comprises a preexponential factor multiplied by an exponential term involving the activation energy and temperature. They showed that particle size was another factor that was needed in the description of kinetics of NP phase transformations.

Among the geochemical and other variables and/or NP properties that may control the NP stability are pH of solution (Finnegan et al., 2007), NP size (Finnegan et al., 2007; Erbs et al., 2008; Liu et al., 2008), presence of ligands, such as, for example, oxalate, which may cause ligand-promoted NP dissolution (Cwiertny et al., 2009), and the presence of coatings or nanocrystals (Liu et al., 2008; Sun et al., 2009b).

4.2.3 Nanoparticle Aggregation

Aggregation of NPs is expected to be a common phenomenon in soils since NP aggregation is observed on many occasions. For example, CeO_2 NPs, which are used as catalysts in the automotive industry and that are expected to reach the terrestrial system in significant amounts, formed aggregates with a mean size of approximately 400 nm when NPs of three different sizes (14, 20, and 29 nm) were exposed to a solution with a pH of 7.4 (Hoecke et al., 2009).

However, one should be aware of the fact that ENPs may show complex colloid and aggregation behavior because aggregation is likely to be affected by particle shape, size (5 nm particles formed larger aggregates compared with 32 nm particles under the same conditions of pH and solid concentrations; Pettibone et al., 2008), surface area, and surface charge of NPs (Handy et al., 2008a; Pettibone et al., 2008). In addition, other factors such as pH, ionic strength, water hardness, and the presence of DOM or other organic compounds may control NP aggregation (Baalousha et al., 2008; Handy et al., 2008a; French et al., 2009). For example, aggregation of 5 nm TiO₂ NPs increased when the contacting solution's pH values were near the PZC, and at any given pH an increase in ionic strength generally resulted in increased aggregation (Domingos et al., 2009). In addition, NPs of titanium dioxide of 4-5 nm diameter readily formed stable aggregates with an average diameter of 50-60 nm at pH similar to 4.5 in a NaCl suspension adjusted to an ionic strength of 0.0045 M (French et al., 2009).

Contrary effects of surface coatings on aggregation are reported in the literature. On one hand, the surface coatings were found to enhance NP aggregation. In experiments conducted with unpurified manufactured Fe-oxide NP (~7 nm) and standard Suwannee River humic acid (SRHA), results indicated that extensive aggregation of NPs began at approximately pH 5–6 and reached a maximum at approximately pH 8.5, whereas with added SRHA, aggregation, which is mainly due to charge neutralization, was shifted to lower pH values of 4–5 and was affected by SRHA concentration (Baalousha et al., 2008). The same effect was observed in another study, where organic acids were found to destabilize NP suspensions (Pettibone et al., 2008), and, in yet another study, results from experiments involving synthetic zinc sulfide NPs and representative amino acids showed a driving role for cysteine in rapid NP aggregation (Moreau et al., 2007).

On the other hand, a study conducted with TiO_2 NPs of 5 nm and Suwannee River fulvic acid (SRFA) indicated that conditions that favored adsorption of the fulvic acid resulted in less aggregation of the TiO_2 NP presumably due to increased steric repulsion among individual NPs (Domingos et al., 2009).

Another scientific issue that remains unresolved is how aggregation affects the available surface area for sorption (sorption extent) and the timescales of adsorption or desorption of contaminants or nutrients from exposed (surface) and remote sorption sites within the aggregate structures. Results from research have demonstrated that the relative reactivity of 5 and 32 nm particles as determined from Langmuir adsorption parameters did not vary greatly despite differences in NP aggregation for these two different size NPs (5 nm NPs form larger aggregates than the 32 nm NPs under the same conditions of pH and solid concentrations) (Pettibone et al., 2008), suggesting that aggregation did not affect the extent of organic acid sorption by anatase particles. However, these authors believe that challenges remain in assessing the available surface area for sorption in NP aqueous suspensions because of aggregation. This is a very important subject that is also related to the interactions of oppositely charged particles and the double layer overlapping mechanism (Qafoku and Sumner, 2002), which is discussed in Section 4.3.

4.2.4 Nanoparticles as Sorbents

Because the chemical and electrostatic interactions at mineral-water interfaces are of fundamental importance in many geochemical, materials science, and technological processes (Ridley et al., 2006), the topic of contaminant or nutrient sorption on NP surfaces has attracted the attention of many researchers in recent years. NPs have high sorption capacity for metal and anionic contaminants such as As, Cr, Pb, Hg, Se (Waychunas et al., 2005), Cu (Madden et al., 2006), hexavalent uranium [U(VI)] (Zeng et al., 2009), NOM (Domingos et al., 2009), and organic acids (Pettibone et al., 2008; Mendive et al., 2009). Contaminant sequestration is accomplished mainly by surface complexation, but sorbed surface species may be encapsulated within interior interfaces of NP aggregates, a phenomenon with significant consequences for contaminant dispersal or remediation processes (Waychunas et al., 2005).

Although some studies have shown that the sorption behavior of NPs of the same type is not size dependent (Ridley et al., 2006; Pettibone et al., 2008), many researchers now believe that NP sorption behavior is size dependent (Zhang et al., 1999; Waychunas et al., 2005; Madden et al., 2006; Abbas et al., 2008; Auffan et al., 2008; Zeng et al., 2009). Different nanosize polymorphs may also exhibit different sorption behaviors for the same sorbate. For example, results from an experimental and theoretical study of aqueous oxalic acid adsorption on anatase NPs (Mendive et al., 2009) were compared with those from a previous study performed by the same authors with rutile NPs (Mendive et al., 2008). Results indicated that differences between surface complexes on anatase and rutile are mainly in the denticity type: in the case of rutile, the most stable species consist of two bidentate surface complexes followed in the third place by a monodentated form, whereas in the case of anatase the formation of four species in which the stability order is reversed with respect to the denticity type is observed (Mendive et al., 2008).

Studies have also demonstrated that NP crystal structure may be manipulated in some fascinating ways affecting NP sorption properties. For example, ZnS NPs with a mean diameter of 3.2–3.6 nm, which were synthesized and treated with different low-temperature procedures, possessed a dramatic range of interior disorder, and a direct correlation was found between the strength of surface–ligand interactions and interior crystallinity (Gilbert et al., 2006b).

Factors such as soil solution pH and ionic strength, isomorphic (elemental) substitution in the NP crystal structure, and NP aggregation may have an important impact on the sorption behavior of NPs. The pH and ionic strength effect on adsorption was investigated, for example, in experiments with TiO₂ NPs of 5 nm and SRFA (Domingos et al., 2009). The effect of Al substitution on magnetite NP sorption behavior was evaluated in presence of the organic molecules benzoquinone and carbon tetrachloride (Jentzsch et al., 2007). The effect of aggregation on sorption was studied in ZnS NPs (similar to 2–3 nm sphalerite) and the binding energy of water molecules, and, thus, the strength of interaction of water was highest in isolated NPs, lower in NP aggregates, and lowest in bulk crystals (Zhang et al., 2007).

4.2.5 Interfacial Electron-Transfer Reactions

NPs may be involved in interfacial electron-transfer reactions with either redox-sensitive elements that sorb to NP surfaces (heterogeneous electron transfer) or microorganisms that are attached directly to the NP surfaces. In addition to the direct electron transfer mechanisms, it is likely that microorganisms may also employ the indirect route (via intermediate electron carriers) to transfer electrons to NPs. Results from studies conducted with hematite NPs and *S. oneidensis* MR-1 suggested that this bacterium employs both indirect and direct mechanisms of electron transfer to hematite NPs (Bose et al., 2009). The results from this study also suggested that Fe(III) reduction rates depend on many factors, such as the NPs' aggregation state, size, shape, and exposed crystal faces (Bose et al., 2009).

For example, the differences in hematite behavior as a function of size and the rates of Mn²⁺ (aq) oxidation by hematite in the presence of oxygen have been determined in a recent study (Madden and Hochella, 2005). These authors argued that the acceleration of electron transfer rate for the reactions promoted by the smallest particles is rationalized in the framework of electron transfer theory. According to this theory, the rate depends on three factors: the electronic coupling between initial and final electronic states, the substantial reorganization energy for solvent and coordinated ligands between initial and final states, and the free energy of reaction (corrected for work required to bring reactants together) (Madden and Hochella, 2005). In two other studies, the significance and effect of NP size distributions were explored for heterogeneous Mn(II) oxidation on hematite NP surfaces (Madden and Hochella, 2008), and the reactivity of two types of nanosized, zero-valent Fe were found to react more rapidly than microsized zero-valent Fe based on massnormalized rate constants, although surface area-normalized rate constants did not show a significant nanosize effect (Nurmi et al., 2005).

The aging effect on electron-transfer reactions was investigated in zero-valent nano-Fe (Sarathy et al., 2008), and the changes in (i) the composition and structure of the particles and (ii) the reactivity of the particles (by carbon tetrachloride reaction kinetics, electrochemical corrosion potentials, and H-2 production rates) were studied (Sarathy et al., 2008). Results showed that Fe-H $_2$ becomes more reactive between 0 and 2 days of exposure to water and then gradually loses reactivity over the next few 100 days.

4.3 Nanoparticle Controls or Impacts on the Extent and Timescale of Soil-/Geo-Processes

The discipline of environmental soil/geo nanoscience is in its infancy, mainly because the study by conventional methods of the complicated behavior of the ENPs that are present in heterogeneous natural media was in the past, and in many respects, it is still nearly impossible. Although review papers on NP behavior and ecotoxicity are now available (Gilbert and Banfield, 2005; Lead and Wilkinson, 2006; Nowack and Bucheli, 2007; Handy et al., 2008a, 2008b; Ju-Nam and Lead, 2008; Klaine et al., 2008; Navarro et al., 2008b; Nowack, 2009a, 2009b), based on the rudimentary knowledge that is currently available (Nowack, 2009b), many challenges remain. The effect of ENPs on the extent and rate of terrestrial chemical, biological, and hydrological processes and reactions is far from being understood.

The complexity of terrestrial ecosystems is remarkable. ENPs may interact in different ways not only with each other but also with a variety of aqueous species and an array of solid particles and soil organic matter (OM) changing significantly or dramatically the nano-, micro-, and macroscale surrounding environment. Soil particles may exhibit permanent surface charge (e.g., micron-size

phyllosilicates) or variable-surface charge (e.g., nanosized metal oxides and hydroxides). Interactions between these micron-size and nanosize particles can lead to the formation of surface coatings and colloid assemblages possessing different properties than their individual constituents. However, much of our knowledge of the behavior of soil particles is derived from experiments conducted with single-phase systems (Bertsch and Seaman, 1999). Although these investigations have improved our understanding of the physical and chemical properties of individual soil particles, the results cannot be readily extrapolated and used to understand the behaviors of the complex assemblages that are present within natural soil and sediment systems (Sumner, 1995; Bertsch and Seaman, 1999).

Heterocoagulation reactions between oppositely charged oxide ENPs and larger phyllosilicate colloids may have a considerable impact on colloidal stability, particle size distribution, reactive surface area, and adsorption reactions (Sumner, 1963a, 1963b; Sumner and Davidtz, 1965; Sumner and Reeve, 1966; Qafoku et al., 2000; Qafoku and Sumner, 2002; Qafoku et al., 2004b). For example, positively charged Fe (hydr)oxide ENPs can coat the negatively charged phyllosilicate surfaces blocking or occupying surface adsorption sites and, as a result, affect the extent of solute adsorption. Overlapping electric double layers of the particles may notably induce unique electrostatic conditions, which are a function of the interplay of NP dimensions and the Debye length (controlled by the ionic strength) (Qafoku et al., 2004b). A full understanding of the nature and magnitude of the interactions among soil particles and ENPs of different types, and how these interactions affect the extent and timescales of different soil-/geo-processes, will take some time to achieve. In addition, in order to improve predictive nutrient mobility and contaminant migration in surface and subsurface environments, interactions between ENPs, soil solution, and other soil/sediment matrices require detailed

Nanoscale studies in terrestrial ecosystems have recently intensified for mainly two reasons. First, methods to isolate and characterize ENPs and state-of-the-art techniques and equipment that have been developed only in recent years have increased significantly our ability to probe phenomena, processes, and reactions at the nanoscale, such as those occurring in the nanopores within soil matrices or on the surfaces of the ENP. For example, recently scientists measured the real-time, minute forces that characterize interactions between living cells of S. oneidensis (a dissimilatory metal-reducing bacterium) and goethite (α-FeOOH), as a function of the distance (in nanometers) separating the cell from the mineral surface (Lower et al., 2001). In another recent study, the environmental importance of the micrometer-to-submicrometer topography variations of fluid-rock interfaces that govern the fate of chemical elements was demonstrated (Fischer et al., 2009).

Second, as mentioned in the previous sections, the industrial-scale production and the wide variety of applications and use of MNPs in many industrial and household applications will definitely lead to the release of such materials

in considerable amounts into environments (Nowack and Bucheli, 2007; Ju-Nam and Lead, 2008; Klaine et al., 2008). Such releases will be controlled, in the form of waste disposal, or uncontrolled. Because MNPs pose potential risks to human health and ecosystems (Wiesner et al., 2006), and because MNPs will affect in different ways chemical, biological, and hydrological processes and physical and mineralogical properties of terrestrial ecosystems (e.g., aggregation and formation of clusters, heteroaggregation, catalysis of precipitation, etc.), the debate on the environmental impact of MNPs has become increasingly important (Hofmann and von der Kammer, 2009), and research efforts have recently been focused in this direction. Assessing these effects and environmental risks requires an understanding of ENP mobility, bioavailability, reactivity, ecotoxicity, and persistency (Nowack and Bucheli, 2007; Kahru et al., 2008).

Discussion in this section is focused on the interactions in the ternary systems composed of ENPs, nutrient/contaminant chemical species, and the soil/sediment matrix. Several aspects of the inhibitory and catalytic effects of ENPs on nutrient/contaminant transport, adsorption and desorption, dissolution and precipitation, and redox reactions are explored and discussed in the subsections of this section.

4.3.1 Advective Mobility and Diffusive Mass Transfer

ENPs may be toxic to different soil living organisms and microorganisms and the chances for them to be exposed to ENPs increase with increasing ENP mobility. Some studies have demonstrated that ENPs may easily move through the soil profiles. For example, results from a study of ${\rm TiO_2}$ NP transport behavior through saturated homogeneous soil columns showed that ${\rm TiO_2}$ could remain suspended in soil suspensions even after 10 days, and the estimated transport distances of ${\rm TiO_2}$ in some soils ranged from 41.3 to 370 cm (Fang et al., 2009).

In addition, topsoils and subsoils are often rich in nutrients or could be contaminated with trace metals, and it is important to understand how different processes govern their transport to fresh and marine waters (Hassellov and von der Kammer, 2008). ENPs have high sorption capacity for aqueous nutrients and contaminants. The sorbed ions neutralize the ENP electrical surface charge and the ENP: sorbed ion complex can potentially travel longer distances through the soil matrix pores than charged ENPs or ions taken separately. ENPs may, therefore, serve as carriers of contaminants and nutrients, increasing their overall mobility in terrestrial ecosystems. Studies have demonstrated that NPs, such as carbon nanotubes (Schierz and Zänker, 2009), can serve as carriers of contaminants, facilitating their transport through soil profiles via advective and diffusive mass transfer. For example, accelerated transport of Pb associated with Fe oxide NNPs was observed in soil and river samples in Germany and Sweden (Hassellov and von der Kammer, 2008). In another study, carbonaceous MNPs were found to enhance the transport of hydrophobic organic contaminants (HOCs) in porous media because HOC was strongly sorbed to them (Hofmann and von der Kammer, 2009).

It is, therefore, essential to understand the fate and transport of ENPs in terrestrial environment in order to evaluate their potential risks to organisms and/or microorganisms and the possibility for increased contaminant and nutrient mobility, human exposure, and damages to the ecosystems.

The movement of ENPs in soils and through the soil profile is controlled by a number of geochemical variables, such as pH (Guzman et al., 2006b; Schierz and Zänker, 2009), ionic strength (Hassellov and von der Kammer, 2008; Fang et al., 2009), the contents of DOM, OM, humic acid and clay (Fang et al., 2009; Johnson et al., 2009; Schierz and Zänker, 2009), sorption kinetics, and residence time (Hofmann and von der Kammer, 2009), in addition to NP-related properties such as surface charge, size (Hofmann and von der Kammer, 2009), shape, aggregation, surface coatings (Moreau et al., 2007; Joo et al., 2009), and impurities. These examples from the literature clearly demonstrate the complexity associated with studies of these types, which involve an array of variables with possible simultaneous or sequential controls or effects on ENP mobility.

4.3.2 Adsorption/Desorption

Within this subject area, there are at least five important topics to be explored. The first topic is the estimation of the extent and timescale of ENP adsorption to and desorption from different soil minerals or soil materials. For example, in a recent study, it was found that the kinetic rate constants of the adsorption reaction of oppositely charged NPs changed with the aqueous NP concentration (Tretiakov et al., 2009).

The second topic covers the estimation of the extent and timescales of adsorption and desorption of the complex ENP: sorbed nutrient/contaminant on different soil minerals and/or soil materials. Such ENP: sorbed ions complexes are formed, for example, in Andosols of the island of Réunion, which have high Ni concentrations due to the natural pedogeochemical background, and high abundances of natural aluminosilicate ENPs (Levard et al., 2009). Ni is chemically bonded to natural shortrange ordered aluminosilicate ENPs, and this complex represents about 75% of the total Ni in this soil.

The third topic is assessment of the effects of ENPs on contaminant and nutrient adsorption/desorption in soils. For example, force-volume microscopy and a silicon-nitride probe were used to measure changes in adhesion when a patchy overgrowth of Mn oxide nanostructures formed on the surface of rhodochrosite (Na and Martin, 2009). According to these authors, the quantitative mapping of adhesive force can lead to an improved mechanistic understanding of how nanostructure growth influenced contaminant immobilization and bacterial attachment. Research has also demonstrated that Fe-rich NPs compete efficiently with NOM for Pb binding in soils and rivers (Hassellov and von der Kammer, 2008). Another aspect of this phenomenon is ENP competition with aqueous species of contaminants

and/or nutrients for available sorption sites on different sorbents present in soils.

The fourth topic involves the usage of NPs for aqueous contaminant removal and remediation purposes. For example, research work has shown that CuO NPs with a surface area of 85 m² g⁻¹ and 12-18 nm diameter were an effective material for As(III) and As(V) adsorption and may be used to develop a simple and efficient As removal method (Martinson and Reddy, 2009). Other studies have investigated the potential of zerovalent Fe NPs for treatment and remediation of persistent organic pollutants such as hexachlorocyclohexanes (HCHs; C₆H₆Cl₆) (Elliott et al., 2008); the removal of radionuclides and contaminants using apatite, a calcium phosphate mineral, with a nanoporous structure and with a strong affinity for contaminants and radionuclides (Moore et al., 2007); application of a new type of alumina-coated magnetite (Fe₃O₄/Al₂O₃) NPs that were modified by the surfactant sodium dodecyl sulfate (SDS) to increase adsorption capacity, for extraction of trimethoprim (TMP) from environmental water samples (Sun et al., 2009b); and the adsorption potential of pure and iron-doped TiO₂ particles with crystal sizes of 108 and 65 nm, which were subsequently immobilized on sand, for removing arsenic from drinking water (Nabi et al., 2009).

The fifth topic is evaluation and quantification of the controls or effects of different variables on all the adsorption and desorption processes that were described in topics 1–4. One can easily realize that a massive research effort is required to address all these scientific issues. The few examples provided above clearly illustrate the fact that the scientific community has just started to work to address these scientific issues.

4.3.3 Dissolution/Precipitation

ENPs that are present in terrestrial systems may influence the extent and timescales of dissolution and precipitation reactions occurring in soils and subsoils, and this might have an effect on nutrient and/or contaminant mobility in these systems. For example, the in situ Fe(III) reduction was monitored in soils, the mineralogical changes of Fe-oxides were initially studied (Fakih et al., 2008), and then the impact of (bio)reduction on both Fe-oxide dissolution and secondary mineral precipitation and the subsequent effects on As mobility were subsequently estimated (Fakih et al., 2009). Again, this is an unexplored area of research, and definitely studies are required to investigate single and coupled reactions and processes that might affect the extent and timescale of dissolution and precipitation and nutrient and contaminant mobility in natural terrestrial systems.

4.3.4 Electron Transfer Reactions

NP catalytic or inhibitory effects on contaminant and/or nutrient reduction or oxidation in soils and sediments is another topic that is not covered well in the literature as there are only few papers published on this topic so far. Two examples of such studies are included below.

In the first study, arsenite [As(III)] adsorption and oxidation were investigated in the presence of TiO, NPs, and the influence of TiO, NPs on the bioavailability of As(III) was examined in bioaccumulation tests using carp (Cyprinus carpio) (Sun et al., 2009a). Results showed that most of aqueous As(III) was oxidized to As(V) in the presence of sunlight and TiO2 NPs. In the second study, experiments were conducted with a series of Fe(III) sculptured thin films with varied crystallinity (from hematite to ferrihydrite) and nanowire shapes (slanted columnar, clockwise helical, and counterclockwise helical); the dissimilatory metalreducing bacterium S. putrefaciens CN32 was used to measure the bioreducibility of Fe thin films (Tan et al., 2006). Results indicated that bioreduction was controlled primarily by oxide crystallinity. Postbioreduction characterizations of solid phases demonstrated that the mineralogy of the film materials did not change, but surface roughness generally increased with hematite showing the greatest change. Because Fe(III) phases are excellent sorbents and can get involved in redox reactions with redox-sensitive contaminants or nutrients, a better understanding of the redox reactions involving Fe(III) phases definitely helps in a better understanding of the fate of contaminants and nutrient in soils.

4.4 Future Research Directions

Based on the analysis presented in this chapter, a synthetic presentation of future research needs and directions is provided below:

- 1. Studies on NNP occurrence, distribution, and properties are scarce in the literature, and, they are especially rare in the specialized soil literature. Fundamental questions such as the following remain unanswered: (a) What are the identities and concentrations of soil NNPs in different soil orders and along soil profiles? (b) Are there any differences among temperate climate soils, variable charge soils, subsoils, and unconsolidated sediments in terms of NP occurrence, reactivity, and controls on soil-/geo-processes?
- 2. Methods to separate NNP and/or MNP from soil/sediment samples are not developed or described well in the literature. There is a need for methods or well-established protocols on how to separate NNP and MNP from soil matrices.
- 3. The toxic effects of MNP on plants, microbes, and other soil living organisms are only now being assessed. Additional research work is needed before defensible and scientifically based conclusions can be drawn.
- 4. Limited information is available on NNP formation and NNP and MNP stability in the soil systems. Within this topic:
 (a) The conditions and geo/soil variables that promote their formation or control their stability are not well studied; (b) There is no database available for MNP with information about the dissolution or phase-transformation processes they might undergo (thermodynamic and kinetic considerations and controlling variables); (c) The effects of type, size, shape, concentration, aggregation, age formation

- pathway (biotic or abiotic), and the presence of surface defects and/or impurities, on ENP dissolution and stability, are not well understood and covered in the literature; (d) The effects of soil chemical, biological, and hydrological variables on the NP crystal structure formation, stability, and aggregation and kinetics of phase formation and phase transformation are not extensively covered.
- 5. The process of ENP aggregation in terrestrial ecosystems is not well understood and studied. Even general questions still remain unanswered: (a) What are the driving forces behind this process in terrestrial ecosystems? (b) What are the most important geo/soil variables, in addition to pH and ionic strength, which control self- and/or heteroaggregation of ENPs? (c) What is the aggregation effect on the available surface area for sorption and the timescales of nutrient and/or contaminant adsorption to or desorption from exposed (surface) and remote sorption sites within the aggregate structures? (d) How can one predict aggregation occurrence in different soils?
- 6. The molecular-scale mechanisms of contaminants and nutrient adsorption to and desorption from ENPs, and electron transfer reactions involving contaminants and nutrients and ENPs, are not well understood, and this area of research is still developing. Although researchers are addressing scientific issues in these areas, there is much more to be done considering the wide variety of ENPs and the enormous amounts of contaminants and nutrient chemical species that are present in soils. In addition, the combined effects (synergetic or inhibitory, sequential or simultaneous) that may be significant in a system where more than one type of ENP and more than a single contaminant or nutrient are present have not been explored and understood at this moment.
- 7. The information available on ENP advective mobility and diffusive mass transfer and their controls or effects on contaminant and nutrient adsorption/desorption, dissolution/precipitation, and electrons transfer reactions in terrestrial ecosystems is rudimentary and scarce. The potential number of variables that may affect these processes is large, and there is a need for research efforts in all of the areas mentioned above. For example, studies are needed to assess the mobility of single ENP, aggregated ENPs, or ENP: sorbed nutrient/contaminant complexes in soils as a function of one or more physical, chemical, mineralogical, biological, and hydrological variables and properties, as well as NP properties, such as surface charge, size, shape, aggregation, surface coatings, and impurities.

Acknowledgments

I would like to thank Dr. P. Ming Huang (University of Saskatchewan, Canada) for giving me the opportunity to write this chapter, Dr. Donald R. Baer (Pacific Northwest National Laboratory, PNNL, Richland, WA) for providing guidance

and related books and articles, and my manager Dr. Kevin Rosso (PNNL) for supporting me in this effort. PNNL is operated for the DOE by Battelle Memorial Institute under the Contract DE-AC06-76RLO 1830. Some of the figures presented in this chapter were generated in the Environmental Molecular Sciences Laboratory, a national scientific user facility sponsored by the US DOE Office of Biological and Environmental Research and located at the PNNL in Richland, WA.

5.1 Introduction

Soil enzyme activities are the driving force behind all biochemical transformations occurring in soil. Soil is a complex environment where several inorganic and organic components are simultaneously present and exert their action. These components may affect the synthesis, persistence, stabilization, regulation, and catalytic behavior of enzymatic proteins, present at any moment in the soil environment. In soil, enzyme activities outside the cells exhibit altered catalytic, kinetic, and stability properties. For these peculiar features and properties, they can be regarded as "naturally immobilized enzymes." Several studies have demonstrated that clay minerals, organic matter (OM), and organo-mineral complexes are involved in the interaction with enzyme activities and the immobilization of enzymes in soil. Two methodological approaches have been used for understanding the relationships between immobilized soil enzymes and their clay, humic, or humic-clay supports (Gianfreda and Bollag, 1996). The first approach is based on the isolation, purification, and characterization of active enzymatic fractions from soils. In the second approach, synthetic model systems, in which enzymes are artificially immobilized by their attachment to soil components, have been used for studying the properties of soilbound enzymes.

This chapter gives a general picture of the interactions possibly occurring between soil inorganic and organic components and soil enzymes. The effects of the soil components on the performance and efficiency of enzyme activities, the mechanisms involved in their interactions, the role of soil-bound enzymes from an ecological point of view, and their potential for practical purposes are addressed.

5.2 Soil Enzymes as Naturally Immobilized Enzymes

Soil is an extremely heterogeneous microenvironment where physical, chemical, and biological processes occur simultaneously among numerous inorganic and organic components and living organisms. In this variety of components, enzymatic proteins, and their activity, exert a predominant role because they (a) catalyze all the biochemical transformations occurring in soil; (b) guarantee the exchange of materials among the biotic and abiotic portions of the soil ecosystem; (c) allow the growth, survival, and activity of soil living organisms. All enzymatic processes occur through coordinated and integrated pathways to ensure the correct energy transfer and nutrient cycling and to preserve soil and environmental quality and crop productivity (Dick, 1994; Tabatabai, 1994).

Although soil is expected to contain a large array of enzymes involved in the cycles of the main nutrients (carbon, nitrogen, phosphorus, and sulfur), only enzymes belonging to the four classes EC 1, EC 2, EC 3, and EC 4, cited in Chapter 3, have been detected and assayed in soil. Moreover, each type of soil presents its own characteristic pattern of specific enzymes and an inherent level of enzymatic activity.

The measurement of enzyme activity in soil is still a bottleneck in soil enzymology. Although many papers, book chapters, and entire books have been dedicated to collect and describe methods for assaying enzyme activities in soil, standardized, universally accepted methodologies for determining the activity of a given soil enzyme are still not available. In addition, the variety of experimental conditions adopted by different authors (i.e., different incubation pH and temperature, assay duration, type and concentration of substrate, treatment of the soil before the assay, etc.) often does not allow enzymatic activity values to be compared. As claimed by Gianfreda and Ruggiero (2006), "the conclusion of all the findings so far reported is that unfortunately methodologies, capable of measuring accurately and unambiguously each of soil enzyme components, are not available to date."

As widely accepted, different intracellular and extracellular enzymatic components contribute quantitatively and qualitatively to the overall enzymatic activity of soil (Burns, 1978, 1982; Nannipieri, 1994; Nannipieri et al., 1990, 2002; Gianfreda and Bollag, 1996; Gianfreda and Ruggiero, 2006). The different components can be from bacterial, fungal, plant, or animal origin. A given enzyme can be produced by all these sources in different quantitative and qualitative amounts. Moreover, the various intracellular and extracellular enzymatic active components may have different locations not only in their producing organism but also in the whole soil (Burns, 1978, 1982). They may exist in different states, present different features and properties, and act under a range of different microenvironmental conditions that affect their catalytic behavior (Gianfreda and Bollag, 1996).

Among enzymatic categories, defined and classified differently by several authors (Skujins, 1976; Kiss et al., 1975; Burns, 1982; Gianfreda and Bollag, 1996; Ruggiero et al., 1996), enzymes associated (e.g., adsorbed, entrapped, polymerized, and/or co-polymerized) with inorganic, organic (including soluble or insoluble substrate), and organo—mineral soil components may contribute a large portion of the overall activity of many enzymes. They are considered soil-bound or "naturally immobilized enzymes" and are recognized as mainly responsible for the enzymatic activity shown by a soil in the absence of living cells (Gianfreda and Bollag, 1996).

As reported in earlier and more recent reviews (Ladd and Butler, 1975; McLaren, 1975; Ladd, 1985; Burns, 1986; Kiss et al., 1986; Boyd and Mortland, 1990; Gianfreda and Bollag, 1996; Naidja et al., 2000; Gianfreda et al., 2002; Ahn et al., 2006; Nielsen et al., 2006; Pietramellara et al., 2009), clays, clay minerals, OM, and organo–mineral complexes have an important role in the immobilization of enzymes in soil. This conclusion was mainly derived from results obtained in model experiments

with synthetic clay-, humic-, or clay-humic-enzyme complexes. As discussed recently by Nielsen et al. (2006) and thoroughly studied for the adsorption of extracellular DNA by soil colloids (see review by Pietramellara et al., 2009), proteins can also be released after cell lysis and react with surface reactive particles with other cell constituents.

5.3 Natural and Synthetic Soil Enzymatic Complexes

Two different methodological strategies have been used to investigate soil enzymes, to elucidate their peculiar properties, and to understand the mechanisms involved in the interaction between enzymes in soil and their clay or humic supports. The first approach dealt with the isolation, purification, and characterization of active enzymatic fractions from soils. Various experimental procedures and several biochemical techniques were used for the extraction, separation, and purification of these enzymes. Notwithstanding, very few purified enzymatic proteins were extracted from soils (Tabatabai and Fu, 1992; Nannipieri et al., 1996; Nannipieri, 2006). Indeed, many of the examples reported in literature refer to enzyme-like substances showing enzymatic properties rather than to protein molecules with enzymatic features. Most of these enzyme-like substances contain organic material, very often of carbohydrate nature (Mayaudon, 1986).

Moreover, humus—enzyme complexes are very often extracted from soil by using the experimental procedures usually used in the extraction and purification of humic substances (Nannipieri et al., 1996, Nannipieri, 2006), thus supporting the existence of humus—enzyme associations in soil. No such experimental evidence is available for similar complexes with clay minerals. If short-range ordered mineral colloids are extracted, they are dissolved in the extracting solution. If the enzymes strongly bound to mineral surfaces, they are not extractable.

In the second approach, synthetic model systems prepared under laboratory conditions were used. These consist of placing enzymatic molecules and soil constituents (i.e., pure or "dirty" clays, humic or humic-like substances, organo—mineral complexes) in contact with each other. In this case, adsorption should be the driving mechanism. Although several adsorption studies have been carried out on clay minerals, fewer investigations have been devoted to the adsorption of enzymes to humic substances, probably because of the experimentally established inhibitory effect of humic substances.

The formation of active enzymatic complexes has also been obtained by mixing enzymes and humic precursors and varying the environmental conditions (i.e., nature of the organic constituent [humic acid phenolic component], contact time, ratio between the two components, and presence or absence of an additional biotic or abiotic catalyst).

Particular care must be taken in the preparation of synthetic enzymatic complexes. Indeed, the choice of an enzyme from a source and in a given formulation over the same

enzyme from a different source and/or a different formulation may lead to such contrasting results that completely different conclusions may be drawn on the behavior of the enzyme in response to an applied factor. Therefore, although model studies may be of considerable importance to understanding the real soil, care must be taken in the extrapolation of results obtained with synthetic model systems to natural conditions.

5.3.1 Enzymatic Activities Extracted from Soil

Until recently, studies on the extraction of enzymes from soil were important for elucidating the nature, properties, and complexity of enzyme activities in soil and to understanding their role in soil functionality. Nowadays, such studies achieve a further and more important significance as being essential for soil proteomics, which involves protein extraction from soil (Nannipieri, 2006). Soil proteomics, an aspect of the larger field of environmental proteomics, combined with soil genomics can shed light not only on the presence of some genes (and in turn of some peculiar living organisms) in soil but also on protein synthesis and specific soil functions (Ogunseitan, 1993, 2006 and references therein; Nanniperi 2006, and references therein). The aim of soil structural proteomics is the study of proteins and peptides found in water, sediments, and soils. It is devoted to understand the location and stabilization of extracellular proteins in soil. Analysis of proteins extracted from environmental samples may help to characterize the response of microbial communities to stressful conditions such as contamination with toxic chemicals, starvation, heat, or oxygen levels (Ogunseitan, 2006 and references therein). Study of proteins can also be used as a "fingerprint" to type the diversity in the sample and as an index for monitoring the progress of a biocatalytic reaction "in situ" (Ogunseitan, 1993).

Although experimental procedures for extraction of DNA and mRNA from soil samples are quite well standardized and reliable and reproducible data are usually available (Pietramellara et al., 2009), methods affordable for the extraction of proteins and enzymes from soil still have several deficiencies. Although several improvements have been attempted (Ogunseitan, 2006; Benndorf et al., 2007; Solaiman et al., 2007; Masciandaro et al., 2008), these methods have not been standardized. Indeed, several experimental problems are usually encountered, and most of them are still not solved. This is probably a consequence of the existence of proteins and enzymes in soil as immobilized molecules on soil colloids.

Nanniperi (2006) has exhaustively examined the findings about extraction of enzymes from soil. This author showed that studies were mainly devoted to extracellular hydrolases, selected for their importance in nutrient cycling, for their presumed activity in the extracellular environment, and because their activity can be easily determined in soil. One of the most important difficulties encountered in this approach was the choice of the extracting solution. An efficient solvent system should provide high yields of enzymes, without denaturing effects on protein structure, removal of nonenzymatic soil OM, or undesired lysis of soil organisms. Moreover, no artifacts should appear during soil extraction. Indeed, it is possible that the extracted

enzymes undergo adsorption or entrapment within the solubilized complexes or the extracting compound (like citrate) may interact with inorganic soil components (such as manganese) and the Mn-citrate complex produce a catalytic activity resembling an enzyme (laccase) (Leonowicz and Bollag, 1987).

Salt solutions such as pyrophosphate, phosphate, acetate, citrate, tris-(hydroxymethyl)-aminomethane (TRIS or THAM), tris-borate, borate, etc. have been used to extract enzymes from soil (Tabatabai and Fu, 1992; Nannipieri et al., 1996; Bonmati et al., 1998; Nannipieri, 2006). The most commonly used extracting solutions were sodium pyrophosphate and phosphate because of their capacity to extract OM under mild conditions. Enzymatic preparations showing urease, β -glucosidase, catalase, protease, and phosphatase activities were extracted from different soil types with pyrophosphate (Nannipieri, 2006 and references therein). Most of these enzymatic preparations were humic–enzyme complexes. Further studies were performed to characterize the enzymatic preparations and different enzymatic fractions showing different catalytic activities, and stability properties were obtained (Nanniperi et al., 1996; Nannipieri, 2006).

In previous studies, Mayaudon (1986), using a different experimental procedure based on phosphate-EDTA as the extractant, concluded that most of the free (i.e., not bound to soil colloids) extracellular enzymes in soil are glycoproteins, as they were strongly associated with carbohydrate residues. Their presence usually confers to the enzyme or protein an increased stability to denaturing agents, although difficulty may arise in the extraction and separation procedures.

The use of 67 mM phosphate buffer at pH 6.0 was very efficient in the extraction of a free cellulase from greenhouse soils (Murase et al., 2003). The efficiency of this extracting solution was evaluated against 0.1 M sodium pyrophosphate (pH 7.0) and 0.5 M potassium sulfate (pH 6.6), in recovering the protein quantity and the β -glucosidase enzyme activity from two natural forest soils (Masciandaro et al., 2008). The pyrophosphate extract showed the highest β -glucosidase activity, thus confirming its capability of extracting humic-bound β -glucosidase enzyme in a stable and active form.

An attempt to increase extraction yield for measuring intracellular soil arylsulfatase was made by Fornasier (2002). Bovine serum albumin (BSA) was added to Tris–HCl buffer used as the extracting solution, and a measurable increase (11%) of extracted enzyme was obtained. An improvement of the method was the simultaneous use of BSA, Triton X-100, and bead beating (Fornasier and Margon, 2007). Acid and alkaline phosphomonoesterase and arylsulfatase were extracted at high yield, with negligible amounts of humic substances, from six soils differing in their properties (Fornasier and Margon, 2007).

5.3.2 Formation of Synthetic Enzymatic Complexes

Most of the information on the behavior, performance, and features of soil enzymes has been gathered by studies with synthetic enzyme systems simulating those possibly occurring in soil. Many findings are available in the literature on the preparation, characterization, and properties of different enzymes adsorbed, entrapped, and/or complexed with different natural or synthetic soil constituents by means of several mechanisms. Even in this case, standardized methods are, however, not available for the preparation and characterization of immobilized enzymes resembling those naturally occurring in soil. A handbook entitled *Methods of Soil Enzymology* edited by R. Dick for the Soil Science Society of America is in preparation, and a chapter (coauthored by Gianfreda and Rao) is specifically dedicated to the description of standardized methods for the preparation and characterization of synthetic soil enzymatic complexes.

Three main mechanisms may be envisaged in the preparation of synthetic enzymatic model complexes simulating those present in real soils:

- Adsorption on soil components including mineral soil components, organic matter, or organo-mineral complexes.
- Covalent attachment to soil components, as the results of cross-links between reactive groups on the support and external amino or carboxyl groups of the enzyme.
- Entrapment in polymeric organic materials by different types of processes: the enzyme may be embedded into soil OM either as the result of the polymerization of humic or humic-like precursors through the action of biotic or abiotic catalysts and involving enzymatic molecules or by the entrapment of protein molecules in an organic network made by several small or large macromolecules.

Cation-exchange adsorption mechanisms (Harter and Stotzky, 1971), van der Waals type forces (Hamzehi and Pflug, 1981), and ionic or hydrophobic bonds have been suggested as possible mechanisms whereby enzymes are held to clay surfaces (Boyd and Morland, 1990). Ion exchanges, entrapment within organic networks, ionic bonding, or covalent attachment are the main processes accounting for the stable association between enzymes and humic materials (Ladd and Butler, 1975). Electrostatic forces and van der Waals interactions are enthalpic, whereas hydrophobic interactions are mainly entropic (Quiquampoix and Burns, 2007). As claimed by Quiquampoix and Burns (2007) "the affinity of proteins for various types of interfaces originates in the flexibility of the polypeptide chain and in the diversity of the 20 amino acids that can be classified on an electrical scale as positively, neutrally or negatively charged and on a hydrophobic scale from polar to non-polar."

The most abundant findings have probably been obtained by physical adsorption of different enzymes on supports chosen among soil components. The procedure for the preparation of synthetic enzymatic model complexes involving physical adsorption is a very simple process consisting of incubating, very often under stirring, the enzyme molecule and the support and in separating the solid phase and the supernatant after a given incubation time. The amount of adsorbed enzyme can be simply assessed by measuring the amount in the supernatant and washings and by subtracting it from that initially put in contact

with the adsorbing support. Adsorbed enzymes can, however, be easily removed from their adsorbing support by changing pH, temperature, ionic strength, substrate concentration, or buffer used in the activity assays.

Natural clays such as montmorillonite, kaolinite, goethite, illite, palygorskite, oxides, "dirty" clays, humic acids, organo—mineral complexes, or even soil fractions and whole soils have been used as supports. Enzymatic proteins from different origins and as different commercial preparations have been employed (see reviews by Harter and Stotzky, 1971; Burns, 1986; Kiss et al., 1986, Boyd and Mortland, 1990; Huang et al., 1995, 1999; Gianfreda and Bollag, 1996; Gianfreda et al., 2002).

5.3.2.1 Clay-Enzyme Complexes

The capacity of proteins, including enzymes, to be sorbed on phyllosilicates is influenced by the surface area of clay minerals (kaolinite, illite, montmorillonite) and their ability to intercalate protein molecules, the charge characteristics of both minerals and proteins, and is influenced by the size, shape, and isoelectric point (IEP i.e., the pH at which the protein carries no net charge) of protein molecules, the cation exchange capacity (CEC) of minerals, the nature of saturating cation of the clays, and the pH and temperature of the system (Mc Laren et al., 1958; Harter and Stotzky, 1971; McLaren, 1978; Theng, 1979; Violante et al., 1995).

The contact and the type of interactions occurring between soil surfaces and protein molecules will dramatically reflect in the conformation and stability of the protein structure and in turn in its functionality. If the protein is an enzyme, the interactions may have severe consequences on its activity and catalytic role. According to Norde (2008), two classes of structural stability for proteins, soft and hard, have been identified. Soft proteins undergo modifications of the structure, whereas hard proteins retain the same structure in the adsorbed state. In the first case, a change in the catalytic activity of the adsorbed enzyme is expected, whereas for hard proteins the observed changes in their catalytic behavior will be the result of other effects such as, for instance, a different orientation of the active site, possibly not accessible to substrate molecules. Both phenomena may be influenced by the pH (Quiquampoix et al., 2002).

When considering the impact of surface area on the adsorption of proteins on clay minerals, not only the surface area of the clay but also the size of the protein molecule and its capability to interstratify into the phyllosilicate have to be taken into account. It may be expected that proteins characterized by smaller size and molecular masses should be more easily stratified than greater protein molecules. However, experimental evidence not always supported a significant correlation between the surface area of the clay mineral and the amount of the enzymes adsorbed (Gianfreda et al., 1991, 1992). For instance, it was not possible to ascribe the greatest amounts of invertase and urease adsorbed onto Na-saturated montmorillonite (Gianfreda et al., 1991, 1992) to its larger specific area (700-800 m² g⁻¹ when fully dispersed) and capability to adsorb enzyme molecules on both external and internal surfaces (Harter and Stotzky, 1971; Theng, 1979; Fusi et al., 1989), since no interstratification of both enzymes in the interlamellar spaces of montmorillonite was revealed by x-ray diffraction analysis (Gianfreda et al., 1991, 1992). By contrast, a detectable intercalation was observed with acid phosphatase adsorbed on the same clay (Rao et al., 1996) or tyrosinase on Ca-montmorillonite (Naidja et al., 1995). The gradual shift to higher d-spacing values of the complex observed with increasing amounts of tyrosinase indicates that enzyme molecules were interstratified into the interlamellar species of montmorillonite (Naidja et al., 1995) (Figure 5.1a). This may suggest that with some enzymes the surface area may have only a relative influence on their adsorption and that adsorption on the clay minerals is governed by a higher or lower affinity of a given enzyme for the surfaces of a given clay mineral. When the clay interlayers are already partially or totally preoccupied by polymeric species or noncrystalline oxides of aluminum and iron (Figure 5.1b), steric hindrance to the intercalation of enzyme molecules may occur, and a superficial allocation of protein molecules derives (Rao et al., 1996; Naidja et al., 1997; Safari Sinegani et al., 2005). As demonstrated with montmorillonite coated with varying levels of hydroxyaluminum [Al(OH)x-montmorillonite complexes], tyrosinase, and acid phosphatase, the higher the amount of OH-Al species covering the clay, the greater the amount of the adsorbed enzymes (Figure 5.1b). Ligand exchange or secondary interactions such as Van der Waals and hydrophobic or hydrogen bonds were hypothesized for the immobilization of tyrosinase or acid phosphatase on the Al(OH)x-montmorillonite complexes, respectively (Rao et al., 1996; Naidja et al., 1997).

Other important factors to be considered are the electrostatic forces possibly occurring between the charges present on the clay surfaces and the protein. The surface charge of clay can be pH dependent or pH independent, such as that of Al hydroxides and

oxyhydroxides, or montmorillonite, respectively. The charge of the protein is strictly influenced by its IEP. Below the IEP, a protein will carry a net positive charge, and above it a net negative charge. Several experimental findings have demonstrated that the adsorption of proteins is often greatest when the pH of the system is approximately equal to the IEP of the protein (Harter and Stotzky, 1971; Theng, 1979), thus ruling out a strong importance of electrostatic forces in the interaction between the protein and the clay.

The results obtained in the adsorption of several enzymes, which have similar or different IEP by clays characterized by different charge properties (different point of zero charge), seem to confirm that non-Columbic forces (hydrophobic forces, hydrogen bonding, van der Waal's forces) may take part in the process, and their sum may be greater than the forces of electrostatic repulsions and/or attractions between the protein molecules and the charged clay minerals (Gianfreda et al., 1991, 1992; Violante et al., 1995; Rao et al., 1996; Quiquampoix, 2000 and references therein). In particular, hydrophobic interactions may occur between the protein molecules and the clay surface. Indeed, the surface of the clay may achieve a hydrophobic character if positively charged amino acid side chains of the protein exchange with the hydrophilic counterions on the clay surface (Staunton and Quiquampoix, 1994). If hydrophobic amino acids come in contact with the hydrophobic siloxane layer, the protein structure may easily reorganize itself on the clay. This could lead to an irreversible modification of the protein conformation driven by thermodynamic factors involved in the process. Dramatic changes in the efficiency of the involved enzyme may arise.

Clay-enzyme complexes have also been obtained by covalent attachment. In this case, chemical binding occurs between

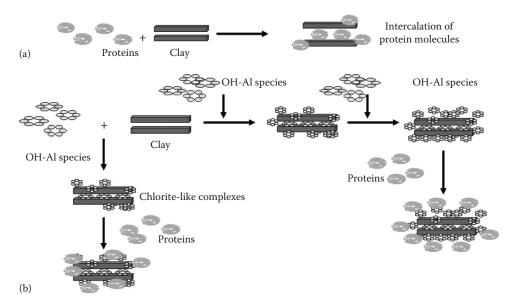

FIGURE 5.1 Interaction of protein molecules with (a) pure and (b) dirty clays. (a) Intercalation of molecules into clay layers occurs with pure clays. (b) Allocation of protein molecules on the external surfaces is favored on dirty clays. The process is much more evident by increasing the amount of OH-Al species on the clay surface. (From Naidja, A., P.M. Huang, and J.-M. Bollag. 2000. Enzyme-clay interactions and their impact on transformation of natural and anthropogenic organic compounds in soil. J. Environ. Qual. 29:678–691; Violante, A., A. De Cristofaro, M.A. Rao, and L. Gianfreda. 1995. Physicochemical properties of protein-smectite and protein-Al(OH)x-smectite complexes. Clay Miner. 30:325–336. With permission.)

enzymes and supports. The enzyme may be directly linked to the support or a spacer or arm is put between the carrier and the enzyme. In the first case, the risk that one or more groups present in the enzymatic active site are involved in the binding is elevated, with evident, negative repercussions on the catalytic activity of the enzyme. Indeed, the active site can be completely masked and therefore not accessible to the substrate. The presence of a spacer, instead, strongly reduces this risk, and the protein can behave as a free enzyme.

In the contest of clay-enzyme complexes, the most used immobilization method has been activation of the support by silanization and grafting through glutaraldehyde (Ruggiero et al., 1989; Sarkar et al., 1989; Gianfreda and Bollag, 1994; Sanjay and Sugunan, 2005; Sanjay and Sugunan, 2007). In particular, the supports were provided by a long arm loading a final chemical group (aldehydic) capable of reacting chemically with reactive amino chain residues of the enzyme (Dick and Tabatabai, 1999). The immobilization process implied a preventive surface modification or an activation step of the immobilizing support. Silanization, that is, the coating of the surface with organic functional groups using an organo-functional silane reagent such as 3-aminopropyltriethoxysilane, was the applied strategy for initial surface modification of inorganic supports, followed by further derivatization to aldehyde groups using glutaraldehyde (Martinek and Mozhaev, 1985).

5.3.2.2 Humic and Humic-Like Enzyme Complexes

Fewer studies have been devoted to the adsorption of enzymes to humic substances probably because of their physicochemical and biochemical complexity. Much evidence is instead available on the entrapment of enzymes in humic fractions or in polymeric aggregates. In both cases, most of the information has been achieved by in vitro studies, although experimental evidence was also provided on humus–enzyme associations extracted from soil (see Section 5.3.1).

Ruggiero and Radogna (1988) studied the interaction of tyrosinase with natural humic acid, extracted from the A1 horizon of an Andosol. Depending on the humic acid concentration, from 32% to 76% of initial tyrosinase was bound to humic acid and retained its catalytic activity with substrate specificity similar to that of the free enzyme (Ruggiero and Radogna, 1988). Infrared spectroscopy suggested that carboxyl and phenolic groups of the humic acid were involved in ionic and hydrogen bond formations with tyrosinase molecules.

To simulate humic substances, a purified humic acid with high anionic properties was put in contact with lysozyme at different pHs (Norde et al., 2008). Lysozyme is characterized by a high IEP (10.5) and thus it is positively charged over a wide pH range, that is, pH < 10.5. The formation of complexes was observed, and it was mainly driven by electrostatic attraction between the oppositely charged components. Dynamic light scattering experiments provided information on the size of the complexes and showed that complexes aggregated to larger structures were found when the IEP was approached. The presence of favorable electrostatic interactions was also supported by

calorimetric studies devoted to evaluate enthalpy (≈energy) of complexation (Norde et al., 2008).

One process possibly occurring in soil is the involvement of enzymatic molecules during the formation of humic substances. In the environment, phenolic compounds, possibly present in soil as biomolecules, wastes, pesticide derivatives, or degradation products, may very often act as humic precursors. In the presence of either Fe₂O₃ or MnO₂, soil and clays, behaving as abiotic catalysts, or phenoloxidases and peroxidases (PODs), acting as biotic catalysts (produced by plants, bacteria, and fungi), the phenolic compounds may undergo oxidative polymerization processes (Bollag et al., 1995; Huang, 1995) (Figure 5.2a). Production of polymeric products can proceed by self-coupling or cross-coupling even with other molecules. Extended polymers of different sizes, shapes, and complexity are generally formed. Both processes are affected by pH, temperature, catalyst amount, contact time, and simultaneous presence of different catalysts (Figure 5.2a). The reaction mechanisms, which involve the production of highly reactive free radicals, are different whether catalyzed by oxidative enzymes or by abiotic catalysts (Gianfreda et al., 2006) and strongly depend on the type of phenolic substrate, as the complexity of phenolic compounds may negatively affect the catalyst and decrease its catalytic efficiency. In addition to polyphenols, other molecules present in soil, but extraneous to the oxidative process, may be involved

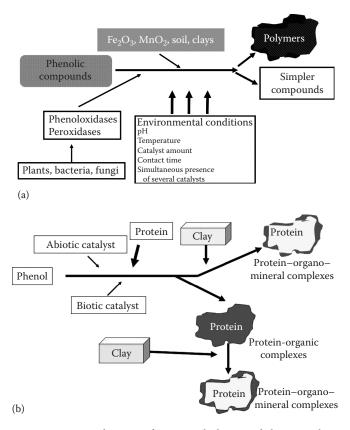

FIGURE 5.2 Catalytic transformations by biotic and abiotic catalysts of (a) phenols and phenolic compounds in natural environments and (b) formation of protein–organo and organo–mineral complexes.

in and/or affect the whole process to a variable extent. In particular, if active proteins are involved, protein-organic or protein-organo-mineral complexes with different structural and functional properties may form (Figure 5.2b).

When the enzyme is involved in the formation of humic substances, several concomitant phenomena may occur and different bonding mechanisms may be envisaged, all affecting the properties of the involved enzyme. As demonstrated by Rao et al. (2007) with a prion protein involved in synthetic humic-like mineral complexes, protein interactions with soluble phenolic polymers, likely involved in the development of humic substances, during or after their formation may occur: (a) through multidentate binding of phenolic polymers to the protein, a process that can become irreversible with time and form insoluble phases (Ladd and Butler, 1975); (b) protein-phenol polymers association through coulombic and/or hydrophobic interactions; (c) protein-phenolic polymeric complexes may transform from flexible soluble structures into insoluble, reticulated structures and microporous micelles in the presence of positive charges (Gianfreda et al., 2002); and (d) quinoid compounds may covalently interact with the protein (Bittner, 2006; Suderman et al., 2006). Multidentate binding is strictly influenced by the structural features of both phenolic polymers and protein and is assisted by conformational flexibility. For instance with protein showing domains with high concentrations of charged residues, like the investigated prion protein (Rao et al., 2007), favorable coulombic interactions with phenol polymers were established. The net result of the above processes is the formation of soluble and insoluble organo-enzymatic complexes that have different catalytic and enzymatic features.

5.3.3 Common and Expected Features of Natural and Synthetic Soil Enzyme Complexes

The main results obtained in the studies with natural and synthetic enzymatic complexes confirm and support what was concluded in two basic studies performed in the late 1980s by Kiss et al. (1986) and Müller-Wegener (1988) and are summarized as follows.

5.3.3.1 Inhibition of the Activity of Enzymes by Both Clays and Humic Substances

In an early but exhaustive review, Kiss et al. (1986) examined the papers published (more than 120 publications) at that time on the interactions between enzymes and clays in soil. The approach followed in the majority of those papers was to investigate the interaction between clays and enzymes under laboratory conditions and to measure the properties of enzymes.

Other studies have since been published in which the same approach or classical inhibition tests are used. For instance, Gianfreda and coworkers (Gianfreda et al., 1991, 1992, 1995a, 1995c; Gianfreda and Bollag, 1994; Rao et al., 2000) investigated the inhibitory effects of pure and "dirty" clays and also of whole soils on the activity of some enzymes (invertase, urease,

phosphatase, laccase, etc.). The kinetics of the enzymes were measured in the presence of increasing amounts of various solid phases, and the kinetic parameters K_m and V_{max} and their variations with the presence of clays were evaluated.

In inhibition studies performed with acid phosphatase from various origins (corn roots, wheat germ, and potato) and montmorillonite, the clay exhibited a strong inhibition effect on the activity of the enzyme (Dick and Tabatabai, 1987; Huang et al., 1995; Rao et al., 2000), and the highest the concentration of montmorillonite in the assay mixture, the greatest was the decrease of the enzyme activity. It is interesting to highlight that the presence of Al(OH)x species on the surface of montmorillonite depressed or partially removed the inhibition of the activity of potato phosphatase by montmorillonite. Indeed, when montmorillonite, which was covered by increasing amounts (3, 9, and 18 meq of Al per gram of clay) of OH-Al species, was used as the support, the inhibitory effect on phosphatase activity decreased from the highest value (>70%) measured in the presence of montmorillonite to about a half-value (35%) when the clay was covered by a greater amount of OH-Al species (Rao et al., 1996). All the minerals significantly reduced the catalytic efficiency, as expressed by the V_{max}/K_m ratio of acid phosphatase, and the higher the amount of the clay, the lower was the catalytic efficiency of the enzyme. An inhibition of more than 80% was observed by Huang et al. (1995) when the activity of wheat-germ phosphatase was tested in the presence of 25-100 mg of montmorillonite. The inhibition effect decreased significantly (from 80% in the case of maximum inhibition to about 35%) when Al(OH) x species were held on montmorillonite surfaces. An opposite effect by OH-Al species coated on montmorillonite surfaces was observed with other enzymes (invertase, Gianfreda et al., 1991; urease, Gianfreda et al., 1992; tyrosinase, Naidja et al., 1995).

It is well known that several humic substances such as humic and fulvic acids, tannins, and melanins, their precursors such as phenols and quinones, and related substances may have inhibitory effects on enzyme activity. The pioneers of this research topic were Ladd and Butler (1969a, 1969b, 1970, 1971, 1975) and Butler and Ladd (1969). In their studies on proteolytic enzymes pronase, carboxypeptidase, and trypsin, they showed that tannins, melanins, and humic and fulvic acids had different inhibitory effects on the activity of the investigated enzymes. In order to identify the humic acid groups mainly responsible for the inhibition, studies were carried out with either modified enzymes (after acetylation) or modified humic acids (after methylation) and under different environmental conditions (presence and absence of inorganic cations). The results obtained indicated that carboxyl groups of humic acids were probably the main groups involved in the inhibition mechanism.

Inhibition by humic substances is not limited to proteolytic enzymes. Oxidoreductases such as PODs (Pflug, 1980; Sarkar and Burns, 1984), malate dehydrogenase (Pflug and Ziechmann, 1981), indoleacetic acid oxidase (Mato and Mendez, 1970), tyrosinase and laccase (Sarkar and Bollag, 1987; Filazzola et al., 1999), as well as hydrolases such as phosphatase, invertase, and urease were also affected by the presence of humic or humic-like compounds and

humic precursors. For instance, Gianfreda et al. (1993a, 1995a, 1995c) and Rao et al. (1998) demonstrated different effects of tannic acid (a starting humic material) on the activity of invertase, urease, and phosphatase. Invertase, with the high content (>50%) of carbohydrate moieties in the molecule, displayed a great resistance to tannic acid inhibitory effect (Rao et al., 1998), probably because it offered a higher resistance than phosphatase and urease to complexation phenomena by the phenolic compound.

The effects of other organic compounds also including precursors of humic substances (such as catechol, methylcatechol, pyrogallol, resorcinol, and gallic acid) on the activity of a fungal laccase were examined in detail by Filazzola et al. (1999). Classical inhibition tests were carried out by testing laccase activity with two substrates, 2,2-azinobis-(3-ethylbenzthiazoline-6-sulfonate) (ABTS) and syringaldazine, characterized by their structural resemblance and their similar reaction mechanisms with enzyme. All phenols inhibited the oxidation of both the substrates. Humic constituents inhibited laccase activity in the order: pyrogallol > gallic acid > resorcinol, and pyrogallol showed the highest inhibition (>93%) at all concentrations. The number of -OH groups and other substituents and the concentration of phenolic compounds influenced the extent of inhibition of the enzymatic activity.

Activation effects by clays (bentonite and kaolinite) on the activity of soil catalase, α -amylase, and cellulase (Novakova, 1988) as well as stimulation effects such as those shown by low concentrations of humic acids on laccase-mediated transformation of xenobiotic compounds were also detected (Huang et al., 2005 and references therein).

Attempts to derive meaningful correlations between soil enzymatic activities and clay or humus content of soil have been addressed in several papers (Gianfreda and Bollag, 1994 and references therein, Gianfreda and Ruggiero, 2006 and references therein). The data did not, however, indicate any unequivocal evidence on the influence of the presence of clays or humic substances on the formation, existence, and stability of active clayor humus—enzyme associations on a quantitative basis.

The main conclusion drawn by most of the performed studies is that the observed inhibition is a consequence of enzyme adsorption on clay surfaces and that catalytic and stability properties are different from those of the same enzymes in a purified form (Kiss et al., 1986).

As to humic substances and their humic precursors, their direct action on the active sites of enzymes as well as a modification of the active site by structural conformational changes may be involved in the phenomenon (Müller-Wegener, 1988). As a consequence, an altered, even pronounced, change in performance of the involved enzyme may result. Having high biochemical heterogeneity and complexity, humic substances may behave as possible substrates in the enzymatic reaction and, in turn, interfere with its equilibrium. Moreover, their cation exchange properties may favor their interaction with cations necessary to the enzyme catalysis (cofactors), directly involved in the stabilization of the active enzymatic structure or in the catalytic mechanism. If the formation of polymeric aggregates

occurs by the action of catalysts or in the presence of additional ions, different consequences on the entrapped enzyme and its catalytic behavior can result.

5.3.3.2 Activity and Kinetic Parameters as Measured for Enzymes Adsorbed on Clays or Linked to Humic Substances as Compared with Free Enzymes

Immobilization often significantly alters the behavior of catalysts because of the changes in the properties of enzymes upon attachment to a solid support. Lower enzymatic activity and reduced substrate affinity have been generally measured with consequent altered values of the kinetic parameters $V_{\rm max}$ and $K_{\rm m}$ values (for definition see Chapter 3), thus indicating a lower catalytic efficiency and a reduced substrate affinity.

For instance, adsorption of acid phosphatase on an inorganic, montmorillonite (M), or organic, tannic acid (T), support considerably reduced the activity of the enzyme (by 80% and 67%, respectively) (Table 5.1). The coating of montmorillonite surfaces with increasing amounts of OH-Al species had a beneficial effect on the activity of the adsorbed phosphatase. Phosphatase activity increased to more than 50% on an Al(OH)x–montmorillonite complex containing 18 meq Al g⁻¹ clay (AM₁₈) (Table 5.1) (Rao et al., 1996). A similar result was not observed with invertase and urease as the greater the amount of Al species on M surfaces, the lower the activity of urease and invertase (Gianfreda et al., 1991, 1992). The beneficial effect of OH-Al species held on montmorillonite surfaces was also observed when investigating the activity of both acid phosphatase from wheat germ (Huang et al., 1995) and tyrosinase (Naidja et al., 1997).

As shown in Figure 5.1b the allocation of protein molecules on the external surfaces may be favored on "dirty" clays. Indeed, OH-Al species occupying the interlamellar sites of the clay impede the access to protein molecules forced to stay on external surfaces (Rao et al., 2000) or favor the orientation of some protein molecules toward positions that may not affect their catalytic activity (Naidja et al., 1997).

Different results were observed when allophanic clay was used as the support (Rosas et al., 2008). In this case, a consistent increase (>40%) in phosphatase activity was observed, but it was slightly lower when manganese and molybdenum ions were present in the reaction mixture (the presence of the two ions should simulate natural conditions of allophanic soils). Moreover, the response was different when the clay was put in contact with the enzyme before or after its interaction with the ions (Rosas et al., 2008).

Activity levels higher or similar to that of the free enzymes were exhibited by a laccase from *Trametes villosa* when adsorbed on short-range ordered aluminum hydroxide (AL) (Ahn et al., 2007) and by glucoamylase adsorbed on montmorillonite (Sanjay and Sunugan, 2005), respectively. Similarly, higher activities than those of the free enzymes were measured for α -amylase, β -amylase, glucoamylase, acid phosphatase, and β -glucosidase adsorbed on composite supports prepared by equal weights of chitosan and activated clay and cross-linked to each other with glutaraldehyde

(Chang and Juang, 2004, 2005, 2007). A preformed network of Ca-polygalacturonate was used for immobilizing acid phosphatase and urease from both bacterial and plant sources (Ciurli et al., 1996, Marzadori et al., 1998a). The support simulated the mucigel present at the root–soil interface with a similar composition and morphology. The adsorption process was carried out in different organic buffers commonly found in root exudates. The highest enzyme activity for free and adsorbed phosphatase was obtained with Na-maleate buffer, whereas a decrease in activity was observed upon adsorption in the presence of the other investigated buffers. A decrease in activity was also observed with the two ureases although it was lower than that measured for the phosphatase.

The phosphatase activity increased when the enzyme reacted with tannic acid in the presence of OH-Al species (AT-P in Table 5.1), OH-Al species and montmorillonite (ATM-P in Table 5.1), or in the presence of soluble and insoluble species of manganese and iron (Table 5.1). Although the presence of Fe or Mn ions did not significantly change the activities of the complexes compared with tannic acid–phosphatase complex, a higher activity level (increase by 50%) and no effect were measured with Fe₂O₃ and MnO₂, respectively.

The complex T-P formed in the presence of Fe₂O₃ and MnO₂ of Table 5.1 are two examples of humic-like enzyme complexes

obtained by contact of phenolic compounds with enzymatic proteins and subsequent polymerization in the presence of biotic or abiotic catalysts (Figure 5.2b). Both the oxides may catalyze the abiotic polymerization of phenolic compounds and Mn oxide is a stronger polymerization catalyst than Fe oxide (Huang, 1990) (Figure 5.2a and b). Evidently, the oxides accelerated the polymerization of tannic acid, but small-size phosphatase-tannic acid-Fe₂O₃ complexes probably formed and phosphatase molecules were adsorbed on the external surfaces of the tannic acid polymers rather than being entrapped within them as probably is the case with Mn oxide. Exposed adsorbed enzymes would give higher activities. The formation of tannic acid-phosphatase polymers and their subsequent adsorption on the oxide surfaces can be also hypothesized (Rao and Gianfreda, 2000). Similar explanations were provided to account for the higher activity shown by urease immobilized on the same phenolic compound and in the presence of the same oxides (Gianfreda et al., 1995c).

On the contrary, the immobilization of acid phosphatase from wheat germ on organo–mineral complexes obtained by intercalation of montmorillonite with representatives of three major classes of biological molecules L-lysine (amino acid), α -D-glucose (carbohydrate), and rhamnolipid (lipid) reduced the activity of the enzyme significantly (Kelleher et al., 2004).

n.d., not determined.

Other precursors of humic substances in soil such as catechol, pyrogallol, resorcinol, etc., have been used for the preparation of organic networks entrapping enzyme molecules (Sarkar and Burns, 1984; Grego et al., 1990; Garzillo et al., 1996; Rao et al., 1999). The phenolic compounds were subjected to polymerization by the addition of the catalyst in the presence of the investigated enzyme, and the properties of the resulting humic-like enzymatic complexes were studied. The catalyst mostly used has been POD. In this case, complexes of only organic nature are obtained. When the catalyst is an oxide, instead of POD, organo–mineral enzymatic complexes are formed.

Experiments performed with phosphatase, when involved in the polymerization of pyrogallol or tannic acid through the action of POD or MnO₂ (Rao et al., 1999), showed that phosphatase interacted much more with tannic acid than with pyrogallol. In the absence of catalysts, pyrogallol was not able to form polymeric aggregates with the enzyme, whereas some polymeric aggregates probably formed with tannic acid. Instead, when the incubation was performed in the presence of POD, the polymerization of pyrogallol was strongly promoted as assessed by the red brown color and the very high E₄/E₆ ratio (equal to 7) of the suspensions, which gives information on the size and molecular mass of humic substances. By contrast, a more efficient effect was demonstrated by the abiotic catalyst on tannic acid. In both the cases, larger enzyme-phenolic copolymers formed, as demonstrated by the browning as well as the decrease in E₄/E₆ ratios of the mixtures (Rao et al., 1999). Stable acid phosphataseresorcinol complexes showing high levels of activity (~90% of the initial enzymatic activity) were also obtained when the phenolic compound interacted with the enzyme in the presence of POD (Garzillo et al., 1996).

High enzymatic activities were observed when the mechanism used in the immobilization process was the chemical binding between enzymes and supports (Gianfreda and Bollag, 1994; Sanjay and Sunugan, 2005, 2006). The kinetic parameters of three enzymes, acid phosphatase, laccase, and POD immobilized by chemical binding to three supports (a montmorillonite, a kaolinite, and a soil with a high silt content and a moderate amount of OM), after their silanization and grafting through glutaraldehyde, are reported in Table 5.2. Two of the three enzymes, laccase and POD, retained relatively high residual activity levels, and laccase immobilized on montmorillonite showed a residual activity higher than that of the free enzyme (Table 5.2). Only phosphatase showed lower activity on all the supports (Gianfreda and Bollag, 1994). Decreased activities were also measured for α -amylase, glucoamylase, and invertase covalently bound onto montmorillonite using glutaraldehyde as spacer (Sanjay and Sugunan, 2006, 2007).

Different effects were observed on the $\rm K_m$ values. Generally, an increase in the kinetic parameter occurred for most of the enzymes immobilized on the various supports. For instance, acid phosphatase adsorbed on $\rm AM_9$ and $\rm AM_{18}$ (Table 5.1) showed higher $\rm K_m$ values than the free enzyme, indicating that the affinity between substrate and enzyme was reduced after immobilization. Accordingly, increased $\rm K_m$ values compared

with those of the free enzymes were displayed by invertase adsorbed on pure and "dirty" clays (Gianfreda et al., 1991); acid phosphatase and urease adsorbed on the Ca-polygalacturonate network or hydroyapatite (Ciurli et al., 1996; Marzadori et al., 1998a, 1998b); alkaline phosphatase adsorbed on Na-sepiolite (Carrasco et al., 1995); urease immobilized by covalent crosslinking through glutaraldehyde on montmorillonite, kaolinite, and two different soils (Lai and Tabatabai, 1992); and α -amylase, β -amylase, glucoamylase, and acid phosphatase adsorbed on composite chitosan-clay supports (Chang and Juang, 2004, 2005).

Lower $\rm K_m$ values, that is, an increased affinity for the substrate, or values approximating those of the free enzymes were instead observed for acid phosphatase immobilized on some organic and organo–mineral complexes (Table 5.1; Kelleher et al., 2004), urease adsorbed on pure and "dirty" clays (Gianfreda et al., 1992), laccase adsorbed on AL (Ahn et al., 2007), and other enzymes adsorbed on clays and organo–mineral complexes of different nature (see reviews by Burns, 1986; Boyd and Mortland, 1990; Gianfreda et al., 2002).

Different explanations are provided to account for the catalytic and kinetic properties of immobilized enzymes.

An *immobilized enzyme* is a protein physically localized in a certain region of space (Martinek and Mozhaev, 1985). After immobilization, enzymes are converted from a water-soluble mobile state to a water-insoluble immobile state (Klibanov, 1983) and become "static enzymes." As a consequence, catalysis by immobilized enzymes acquires a "heterogeneous nature." In fact, immobilized enzymes represent an individual phase separate from the outer solution. The major components of the immobilized enzyme system, that is, the enzyme, the immobilizing matrix and its properties, and how the enzyme is bound to the matrix, are mainly responsible of the kinetic behavior of the immobilized enzyme. Additional variables, such as pH,

^a Expressed as percentage of the activity of the free enzyme.

temperature, ionic strength, pressure, shaking, need for cofactors, substrate delivery, and product removal, may contribute to the environment and thus to the performance of the enzyme.

If the enzyme is placed close to the support surface during the immobilization process, significant surface contributions may influence the performance of the bound enzyme. Indeed, the surface of the support, whether inorganic or organic in nature, may influence the enzyme activity by microenvironmental effects, such as the microenvironmental pH and/or buffering capacity, hydrophobicity and hydrophilicity of the surface, and redox properties.

Moreover, possible conformational changes may occur within the tertiary structure of the protein after immobilization and reflect in a reduced activity of enzymes attached to, or entrapped within, an insoluble support. Denaturation of the enzymatic molecule may arise as a consequence of the high number of linkages between the enzyme and the support and/or the possible interfering interactions between hydrophilic sites and hydrophobic groups of the support and the enzymatic protein, respectively. Stronger negative effects may occur if the immobilization involves groups present in the active site of the enzyme or alter the interactions between the various subunits of the enzymatic molecule, whose integrity is a prerequisite for the catalytic enzymatic function.

The substrate may have restricted mobility and not easily penetrate the active site of the enzyme, possibly because of partial or complete inaccessibility to the substrate as a result of the orientation of the enzyme in relation to the support surface. These effects will be more evident when high-molecular mass substrates such as, for instance, polymeric substrates (e.g., proteins, polysaccharides and nucleic acids) or proteases (which are high-molecular mass proteins) are involved. Immobilized hydrolases, usually, show a marked lower enzymatic activity as well as increased resistance to the attack of proteolytic proteins.

Similar K_m values measured for phosphatase free and immobilized on montmorillonite intercalated with L-lysine, α -D-glucose, and rhamnolipid indicated that the cumulative effect of electrostatic, steric, and conformational changes due to the presence of clay and organic compounds did not affect the access of the enzyme to substrate (Kelleher et al., 2004).

5.3.3.3 Different Activity-pH and Activity-Temperature Profiles Exhibited by Enzymes Adsorbed on Clays or Linked to Humic Substances

Immobilized enzymes usually display different activity-pH profiles, and their optimum pH may move to more alkaline or acidic pH depending on the negative or positive charge of the support, respectively.

For instance, completely different activity-pH profiles were exhibited by phosphatase-clay complexes shown in Table 5.1 (Rao et al., 2000). The activity of the complexes with M, AL, and Al(OH)x-montmorillonite complexes (AM) decreased directly with increasing pH, with maximum activity at pH 4.0

against an optimum pH for the free enzyme in the range 4.5–5.5. However, the decrease in activity was much more acute for phosphatase adsorbed on AM than on AL and M alone, in the order listed. By contrast, the pH of maximum activity as well as the sensitivity to the pH change of the enzyme complexed with Al(OH)x–tannic acid (AT) and Al(OH)x–tannic acid—montmorillonite (ATM) complexes (Table 5.1) were similar to those of the free enzyme. A flatter curve with a shift toward alkaline pH was instead observed for the enzyme complexed with tannic acid.

Activity-pH profiles similar or not substantially different from those of the free enzymes with no differences in pH-optimum values were also observed (Gianfreda et al., 1991, 1992, 1995c; Carrasco et al., 1995; Garzillo et al., 1996; Marzadori et al., 1998a; Chan and Hang, 2004; Ahn et al., 2007; Chan and Hang, 2007). For example, when phosphatase molecules were placed in contact with tannic acid in the presence of Fe ions or OH-Al species, both positively charged, the shift of pH optimum toward the alkaline region observed for the complex with only tannic acid was eliminated, and activity-pH profiles similar to that of the free enzyme were obtained (Rao et al., 2002, unpublished results).

The response to pH of enzymes immobilized on different supports is usually accounted for by microenvironmental effects due to the location of the enzyme in a microenvironment that in the proximity of the support is different from that of the bulk solution. This hypothesis, originating from the double-layer theory, suggests the existence of an interfacial pH effect and presumes that the pH of the thin layer close to the solid surface is different from that of the bulk solution. In other words, the enzyme works at a pH different from that measured. Enzymes immobilized on negative supports usually display a shift in their optimum pH toward the alkaline regions. An opposite shift, that is., versus acidic pH, will probably occur when the enzyme is immobilized in a positively charged support (McLaren and Packer, 1970, Nannipieri and Gianfreda, 1998). In both cases, charged substrates, products, effectors, and/or hydrogen or hydroxyl ions will be differently distributed between the domain of the immobilized enzyme and the outer solution. Electrostatic or hydrophobic interactions between the support and the different components participating in the reaction may occur and reflect in a consequent modification of the microenvironment surrounding the enzyme. Perturbations of the catalytic pathway of the reaction and, consequently, modification of the intrinsic catalytic properties of the bound enzyme may result, and a modification in the catalytic constant or turnover number k_{cat} (see for definition Chapter 3) could occur. This effect can be more pronounced if the kinetic mechanisms involve charged residues of either the substrate or the enzyme, whose charge as well as whose interactions can be enhanced or decreased by the presence of the charged matrix.

A different explanation was provided by Quiquampoix and coauthors in their studies with different proteins and enzymes. Indeed, they demonstrated that a combination of electrostatic and hydrophobic forces determined the pH shift (Leprince and Quiquampoix, 1996; Quiquampoix et al., 1993; Staunton and

Quiquampoix, 1994). The authors provided experimental evidence of pH-dependent modifications of protein conformation, due to attractive electrostatic interactions between positively charged proteins and negatively charged clay surfaces, leading to the unfolding of the enzyme and, in turn, to a decrease in the catalytic activity (Quiquampoix 1987, 2000). Quiquampoix (2008) has recently suggested that the hypothesis of microenvironmental effects has at least three serious drawbacks: (1) "The shift in the optimal pH of activity should give rise to a higher rate of catalytic activity for the adsorbed enzyme than for the enzyme in solution in the alkaline range of pH." For the author, the absence of this experimental evidence is due to "a misleading presentation of the results," which is usually based on "the normalization of enzyme activity values to the maximum value attained for each case, free and bound." (2) "The hypothesis implies that the conformation of the adsorbed enzyme is similar to the conformation of enzyme in solution and can act as a "molecular pH-meter." Experimental evidence to the contrary was provided by the author and coworkers (Leprince and Quiquampoix, 1996; Quiquampoix et al., 1993; Staunton and Quiquampoix, 1994). (3) "The basis of this theory" is not certain. "The tendency of a proton to react with the active site of the enzyme is not given by the proton activity but by its molar free enthalpy...And ... the molar free enthalpy of the proton is the same in the bulk of the solution and at the clay surface."

The microenvironmental theory, however, still has its validity, and several authors continue to apply this theory to explain the changes observed in the activity–pH profiles of enzymes after their immobilization on solid supports.

The influence of the support on the catalytic behavior of enzymes is also evident by the activity-temperature curves (Nannipieri and Gianfreda, 1998 and references therein). For instance whereas the activity of free phosphatase increased by increasing the temperature from 0°C up to 60°C and reached its highest value at 50°C-55°C, a less dependence on temperature was, in general, exhibited by phosphatase immobilized on the inorganic supports shown in Table 5.1 (Rao et al., 2000). The values of the thermodynamic parameters E_a and ΔH_a (activation energy and enthalpy of activation) confirmed the existence of only one rate-limiting step at different temperatures, and their increased values, measured for some of the studied complexes, indicated that different reaction mechanisms were probably followed by immobilized phosphatase. Similar results were obtained with other enzymes immobilized on various supports (Carrasco et al., 1995; Chang and Juang, 2004, 2005).

Thermodynamic studies performed on wheat germ phosphatase, when immobilized on montmorillonite intercalated with L-lysine, α -D-glucose and rhamnolipid, suggested that catalytic activity on the lysine and rhamnolipid intercalated surfaces was more spontaneous and favorable than that of pure clay (Kelleher et al., 2004) and was preserved at temperatures as low as 10° C.

The changes in the activity-temperature profiles usually shown by immobilized enzymes are indicative of a different sensitivity (and often of an increased stability) of the immobilized enzyme to temperature exposure (see below).

5.3.3.4 A Stabilization Effect of the Enzyme Molecules against Several Denaturing Agents (Biological Degradation, Proteolysis, Thermal, and Chemical Deactivation) by Immobilization on Clays or Humic Substances

The most remarkable feature of enzymes after their immobilization on solid supports is an achieved resistance and, in turn, an increased stability to various denaturing agents.

The results shown in Table 5.1 indicate the stability of acid phosphatase complexes to two denaturing agents such as temperature and proteolytic enzymes. Increase or decrease in stability to one or both the agents was monitored. In several cases, complex deactivation mechanisms were demonstrated by both free and immobilized enzymes when exposed to temperature (Gianfreda et al., 1991; Gianfreda et al., 1995c; Rao et al., 2000; Rosas et al., 2008). When the residual activity was plotted as log activity vs. deactivation time, a double-slope pattern was observed. Such behavior is usually described by a two-step series mechanism involving the formation of an intermediate less active form from the native enzyme, evolving to a final inactive conformation of the protein. According to fitted mathematical models, it is possible to fully describe and quantify the phenomenon (Gianfreda et al., 1985).

In comparison with the free enzyme, the complexes of phosphatase with AT and ATM showed a gain in activity of about 40% and 48% after thermal deactivation at 60°C and of about 44% and 48% after 24h exposure to a protease (K protease), respectively (Table 5.1). A similar beneficial effect on the stability of phosphatase-tannate complex was observed when Fe ions or MnO₂ were involved in the complex (Table 5.1). The two complexes with the highest values of activity after 2h exposure to 60°C showed also the lowest sensitivity to the action of the proteolytic agent (Table 5.1). Higher stability to pH, temperature, and proteolysis was shown by acid phosphatase-polyresorcinol complexes, thus supporting the hypothesis that secondary linkages not affecting the conformation of the enzyme but assuring that protection against denaturing agents occurred (Garzillo et al., 1996). Less sensitivity to temperature was also observed with other enzymes such as tyrosinase (Naidja et al., 1997) or POD (Shen and Tu, 1999).

Experimental evidence of the protective mechanism probably built up by the clay and humus colloids was earlier provided by Lähdesmäki and Piispapen (1992) who studied three exoenzymes (protease, cellulase, and amylase) in untreated humus samples, their alkaline extracts and the protein fractions obtained by gel filtration, subjected to several denaturing factors. Results suggested that the fractionation and the dilution damaged or destabilized the protective mechanism created by the soil colloid (clay and humus, present in the unfractionated samples), which preserve soil enzyme activities against certain environmental and other physicochemical changes.

Reusability (i.e., operational stability) of immobilized enzymes has been thoroughly investigated. For example, acid phosphatase or β -glucosidase immobilized on composite

chitosan-activated clay bead maintained high levels (even 90%) of its original activity after 50 times of reuse (Chang and Juang, 2004, 2007). Similar results were also obtained with α -amylase, β -amylase, and glucoamylase (Chang and Juang, 2005).

An increased reusability was often shown by enzymes covalently linked to their support. Continuous reusability for a long period and a greater operational stability were shown by invertase covalently bound or adsorbed on acid activated montmorillonite (Sanjay and Sugunan, 2006). X-ray diffractograms (XRD, nuclear magnetic resonance (NMR), and N_2 adsorption measurements and activity assays performed in a fixed bed reactor gave details on the location of the enzyme onto the clay, on the mechanism and the enzyme groups involved in the immobilization process, and on the catalytic and stability properties of the immobilized enzyme. Similar findings were obtained with α -amylase, glucoamylase, and invertase (Sanjay and Sugunan, 2005, 2007) immobilized onto the same montmorillonite via adsorption or covalent binding (Sanjay and Sugunan, 2005, 2007).

Laccase and POD covalently immobilized on clays and soil showed higher residual activity after 4 month storage at 4°C (Table 5.2) and further peculiar properties, such as reusability in systems simulating real environments, that could be used to solve pollution problems in contaminated soils (Gianfreda and Bollag, 2004) (see below).

An increased stability of enzymatic proteins is the result of an intact three-dimensional structure or conformation. The spatial structure of enzymes has a little plasticity so as to be modified during catalytic reaction as a result of several factors. Dramatic changes in protein conformation may occur and reflect in more or less pronounced reduction in enzyme activity.

Several mechanisms have been envisaged in the stabilization of enzymes upon their immobilization on solid supports (Gianfreda and Scarfi, 1991 and references therein): covalent (mono or multipoint) bindings to an insoluble support may contribute to an increased rigidity and a consequent decreased unfolding of the protein structure; "cage effects" inside a polymeric gel; changes in the enzyme microenvironment; steric hindrances leading to a reduced molecular mobility and capacity of unfolding, and an increased inaccessibility to microbes or proteolytic enzymes.

As also underlined in Chapter 3, immobilization of enzymes on clay minerals and/or humic substances is responsible for the increased stability often shown by soil extracellular enzymes (Burns, 1982; Nannipieri et al., 1994). Whereas the stability of a native enzyme is established by its intrinsic structural features, that of an immobilized enzyme would be affected by several factors dealing with both the properties and nature of the immobilizing support, the type and number of bonds or interactions occurring between the support and the protein molecule, the availability for the protein molecule to preserve some free conformational changes, the environment surrounding the molecule, and the conditions involved in the immobilization process. For instance, the complex formed after interaction of tyrosinase with natural humic acid (Ruggiero and Radogna, 1988) showed a lower stability to both temperature and proteolytic

attack probably because the physical state of the organic matrix changed with increasing temperature and a subsequent hindrance of the enzymatic active site occurred.

The increased stability to temperature exposure often shown by immobilized enzymes could also reflect in different activity—temperature profiles. At high temperatures, the immobilized enzyme will show higher activity than that of the corresponding free enzyme, thus confirming that minimization or prevention of conformational changes in the protein's tertiary structure induced by increased temperatures probably occurred.

The stability to protease attack is consistent with the characteristics of an enzyme entrapped in an organic or organo-mineral complex. Proteases are high molecular proteins, and their attack can be prevented by the shield formed by the organic matrix around the enzyme. The shield may hinder the movement of proteases toward the enzymes without hindering the diffusion of substrate to and of product from the active site.

5.4 Ecological Role of Enzyme-Soil Component Interactions: Carbon Turnover and Storage and Transformation of Nutrients

Soil extracellular enzymes have a fundamental role in the cycling of compounds; in the decomposition of OM with production of inorganic forms of carbon, nitrogen, phosphorus, and sulfur; and in the gain of energy from complex substrates. As depicted in Figure 5.3a, microorganisms (and in part plant roots), which are mainly responsible for biotransformation occurring in soil, release enzymes that are active close to (ectocellular) or at a distance from (extracellular) the cells to degrade insoluble or macromolecular substances such as lignin, carbohydrates, proteins, lipids, and nucleic acids and to allow their use as both nutrient and energy sources (Figure 5.3b). Indeed, although soluble substrates are easily taken up by microbial (and root) cells, insoluble or complex substrates must be broken down into partially degraded or oxidized, simpler compounds that can easily be taken up by cells (Figure 5.3b). Oxidoreductases and hydrolases will act concurrently in the biogeochemical cycles of the main nutrients to assure the biological activity of the soil. Their production is, therefore, controlled by several factors including, at the organism level, the pairing of low-level constitutive synthesis with induction-repression pathways and, at the microbial population and community levels, the quorum-sensing systems that regulate unique and varied cellular responses as well as protection from competing microbial communities (Allison et al., 2007).

In an earlier paper, Burns (1982) described the ecological role of soil enzymes attributing a specific role to the category of extracellular or cell-free enzymes, very often present as soil-bound enzymes. These soil-bound enzymes are persistent in soil, and as such they may be immediately available to transform substrates arriving in the soil. Their activity does not need an induction period to manifest. By contrast, cell-associated enzymes are

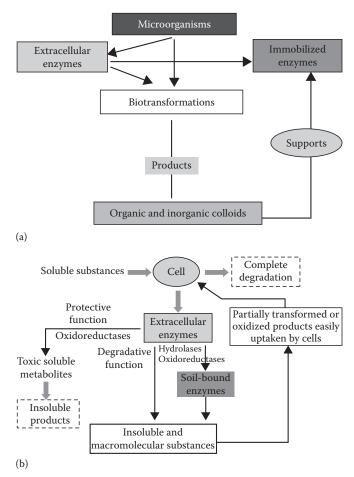

FIGURE 5.3 Role of (a) microorganisms in soil biotransformation and of (b) extracellular enzymes in cell metabolism.

very often produced as inducible enzymes and therefore a short or even long period is necessary before they may develop their activity. Moreover, the rapid transformation of macromolecular substances could lead to simpler compounds possibly acting as inducers of other enzymatic proteins. Since they can easily enter the nearby cells, the synthesis, production, and release of additional extracellular enzymes can be activated, thus enhancing the transformation potential of the soil. Moreover, extracellular enzymes also have the capability of conferring to microorganisms the possibility of reaching and using organic substances embedded in the microporous volume of soil (Quiquampoix and Burns, 2007).

The inorganic and organic derivatives of the more essential macro nutrients C, N, P, and S are involved in complex enzymatic reactions taking place within living (mainly microbial) cells and in the soil solution. A continual interplay of mineralization and immobilization processes brought about by the activities of intracellular and extracellular enzymes affects the availability of nutrients in the soil and thus their importance in crop production. On this basis, a correlation between nutrient availability and enzyme activities in soil do exist, but it is very difficult to identify and quantify the cause–effect relationship between the activity level of a given enzyme and the biochemical

fate of a nutrient. This becomes more difficult when complex substrates like different litter substrates are considered. Indeed, the mechanistic link between the production of extracellular enzymes by microorganisms and litter decomposition is still poorly understood (Burns, 1982; Allison and Vitousek, 2004).

As outlined in the previous sections, the interactions of extracellular enzymes with soil components will substantially affect their behavior and consequently their ecological role.

A major contribution to this topic has recently been made by Allison and coworkers (Allison and Vitousek, 2004, 2005; Allison, 2005, 2006a, 2006b; Allison and Jastrow, 2006; Allison et al., 2007) who elaborated most of the concepts already hypothesized by Burns (1982). An interesting approach to the ecological role of extracellular enzymes was suggested by Allison (2005) who introduced the concept of "cheaters," that is, microbes that do not synthesize enzymes but use products. As depicted in Figure 5.3b, the majority of microorganisms rely on extracellular enzymes for their foraging and survival. This observation led the author to pose several questions "When do microbes produce extracellular enzymes? What costs are involved? What is the fate of secreted enzymes and how effective are they?" (Allison, 2005). Reliable answers to these queries can help understanding the importance of the interactions between microbial and chemical substrates in driving "fundamental ecological processes." The products formed by the action of extracellular enzymes produced by some microorganisms can be used by "cheaters," thus competing with the producers and lowering the efficiency of the secreted enzymes for the growth and survival of their originating cells. Results shown in the previous sections, however, demonstrated that several extracellular enzymes might persist in soil as a stable and active (even if reduced) enzymatic pool. Therefore, an integrated model considering all these situations from an economical point of view was proposed by Allison (2005). A simulation model was established in which the influence of competition, nutrient availability, and spatial structure on microbial growth and enzyme synthesis was examined. Simulation was reiterated by changing C, N, or P supply, and the author concluded that cheaters were favored by conditions in which the cost of enzyme is high, whereas lower rates of enzyme diffusion favored producers. Moreover, carbon mineralization, microbial growth, and enzyme production were limited by nitrogen supply because enzymes with a high content of N-units require high levels of N sources (Allison, 2005). In a previous paper, Allison and Vitousek (2005) assumed that resource limitation could constrain the production of enzymes that, according to the economical theory, should increase when simple nutrients are scarce and complex nutrients are abundant. The authors monitored the activity of phosphatase (P cycle), \(\beta\)-glucosidase (C cycle), and glycine aminopeptidase (N cycle) in an infertile tropical soil after supplying it with C, N, and P nutrients under different combinations of complex and simple nutrient additions and evaluated the relationships between resource availability, extracellular enzyme production, and nutrient dynamics. The most relevant results to the topic of the present chapter was that "microorganisms produce enzymes according to 'economic rules,' but a substantial pool of mineral-stabilized or constitutive enzymes mediates this response" (Allison and Vitousek, 2005). A drawback of these studies is that only one enzyme was considered for each nutrient cycle. As clearly established by Nannipieri et al. (1990), a single enzyme activity cannot be representative of complex metabolic processes such as C, P, and N mineralization.

The extracellular production of enzymes and their consequent activity in soil are of pivotal importance in the carbon cycle, that is, in the decomposition and/or storage of carbonaceous substrates, and consequently they may have potential effect on global climate. Indeed, levels of CO₂ in the atmosphere and their effect on global climate are strongly controlled by the cycling of C compounds in the environment, mainly in the soil (soil is a major carbon sink resulting in reduced atmospheric methane and carbon dioxide [two of the main greenhouse gases]). The decomposition of OM and the sequestration of carbon in soil are affected by several phenomena, all acting simultaneously: mineralization by microbial metabolism, protection of OM by its adsorption and entrapment on/in soil minerals, and formation of soil aggregates not easily accessible to microbial attack.

As reported earlier, extracellular enzymes may have a strong influence on all these processes because they convert complex and insoluble substrates into smaller products (Figure 5.3b). On the other hand, organic products or even more complex, undecomposed materials may be sequestered in soil through the action of oxidative enzymes and production of polymeric materials and humus substances (Figure 5.3b). In this complex scenario, not only carbon-degrading enzymes involved in the degradation and/or polymerization of C-substrates but also those involved in the cycling of P- and N-substrates are important, as P and N are essential nutrients for microbial growth and enzyme synthesis (Allison and Jastrow, 2006; Allison et al., 2007). The interaction of these enzymes with soil and their influence and control on C balance were discussed by Allison and Jastrow (2006) by hypothesizing that "minerals and aggregates could enhance C stability by physically impeding the enzymatic degradation of C compounds" and "enzyme activities would be greater in soil fractions with rapid C turnover, such as particulate organic matter (POM), but lower in fractions with slow turnover, such as clay-sized particles." The activities of three enzymes involved in the C-cycle (β-glucosidase, cellobiohydrolase, and polyphenol oxidase), two in the N-cycle (N-acetyl-glucosaminidase and glycine aminopeptidase), and phosphatase for the P-cycle were tested in macroaggregates, microaggregates, and the claysized fractions across a prairie restoration chronosequence in Illinois, United States (Allison and Jastrow, 2006). The immobilization of both enzymes and carbon substrates on mineraldominated fractions reduced the production of enzymes as well as their activity, resulting in slowing down the carbon turnover. By contrast, immobilization of enzymes and carbon substrates occurred rapidly in POM fractions. These results still confirm the main role of the interactions between extracellular enzymes and soil components in the turnover and persistence of carbon in the environment. The presence of the far larger pool of organic C in soils would be a consequence of the constraints

to its decomposition by extracellular enzymes as well as by the chemical properties of humic compounds and interactions of C with soil minerals (Allison, 2006a).

To clarify the dynamics of extracellular enzymes as either bound or free within the soil, experiments were performed to determine the turnover rates of some enzymes (phosphatase, β-glucosidase, polyphenol oxidase, N-acetyl-glucosaminidase, and urease) within a well-characterized volcanic soil. The effects of common soil compounds such as ferrihydrite, allophane, and humic acids on enzyme stability and activity were also examined (Allison, 2006b). According to results previously discussed, allophane had a strong positive effect on most enzyme activities, whereas ferrihydrite had a weak positive effect on some enzymes and humic acids strongly inhibited enzyme activity (Allison, 2006b). Probably the most relevant finding from these studies was that stabilization and inactivation of enzymes on soil minerals and humic acids have to be considered and integrated into conceptual models of enzyme function. For instance, the composition of mineral and humic compounds of a soil could justify the ecosystem-specific responses of soil enzymes to environmental perturbations (such as CO₂ or nitrogen fertilization). As Rosas et al. (2008) demonstrated with synthetic enzymatic systems, Andisols, rich in allophanic materials, are expected to have high potential enzyme activity because of their ability to immobilize and stabilize enzymes.

Scheel et al. (2008) studied the effects of precipitation and adsorption of extracellular enzymes on a stable soil OM fraction on the performance of enzyme function for carbon mineralization. The OM fraction was obtained by precipitation of dissolved organic matter (DOM) with aluminum. The activities of eight extracellular enzymes, involved in C degradation (chitinase, cellobiohydrolase, β-glucosidase, glucuronidase, laccase, and xylosidase) and of leucine-aminopeptidase and acid-phosphatase involved in N and P cycles, respectively, were studied in OM fractions that were obtained from two top horizons of two forest soils and precipitated at different Al:C ratios and pH values to achieve a large variation in composition and C mineralization. The investigated enzymes were all functioning in precipitated OM. The results in terms of amounts of precipitated DOM, of strong correlation between enzyme activity levels and C mineralization, and of disappearance of the latter led the authors to conclude that precipitated extracellular enzymes were in a functional state and played a significant role in the turnover of a stable soil organic matter fraction, like precipitated OM, during the initial degradation phase, and that the stability of precipitated OM is mainly governed by chemical properties and not by lack of enzymes.

A confirmation on the effect of soil environment on the performance of enzyme function was provided by George et al. (2007) in comparative studies performed on the mobility, stability, and catalytic activity of phytase from two fungal sources. Phytase is the enzyme responsible for the hydrolysis of inositol phosphates, the largest fraction (>50%) of organic P compounds in soil, and therefore affects the biological availability of these compounds. The enzymes were added to soil suspensions of three soils

(a Spodosol, an Oxisol, and an Alfisol), and their activities in the solution and in the solid phase were measured. The two enzymes exhibited different efficiencies in the three soils according to their physicochemical differences; these strongly influenced the adsorption of the phytases, which in turn affected their stabilities and resistance to microbial degradation. Again, the importance of the interactions between enzymes and soil components to the availability and transformation of nutrients in soil was confirmed.

Knight and Dick (2004) suggested that soil-stabilized β -glucosidase activity (e.g., the abiotic fraction of the enzyme stabilized by its association with soil colloids) could act as a soil quality indicator to discriminate between field management effects. Since interaction between enzyme and soil colloids would not show large temporal variability, accumulation or degradation of this stable form of the enzyme will proceed at "a steady pace over time under a given management system."

5.5 Interaction of Soil-Bound Enzymes with Anthropogenic Organics and Their Potential for Ecosystem Restoration

Polluting substances are continuously released in the environment as a consequence of the impact of man's activity on the biosphere. They accumulate in the ecosystem and alter and disturb its natural balance. Among the environmental compartments, soil can be considered a natural sink for anthropogenic contaminants.

The pollution of the environment, and in particular of soil, poses a great concern not only to devise remediation technologies suitable for an effective restoration of polluted sites but also to elucidate the possible influence of pollutants on the many vital functions that soil performs for the environment and society.

In restoration and recovery of soils from pollution as well as in understanding pollution effects on soil functions, free or bound extracellular enzymes have attracted the attention of many researchers (Dick and Tabatabai, 1999; Naidja et al., 2000; Gianfreda and Bollag, 2002; Gianfreda and Rao, 2004, 2008 and references therein).

Any study of the impact of any influencing factor on soil enzymatic activities has to take into account the complexity of these and their existence under several enzymatic categories or "states," each with its "own" catalytic features and characteristics. As a consequence, each enzymatic category may respond in a different way and with a different intensity to the action of a given factor. Moreover, pollutants, and in general xenobiotics, may present irreversible and reversible direct and indirect effects on soil enzyme activities. In the first case, reversible binding may occur between the xenobiotic and/or its degradation products and the intra and extracellular enzymes, with a resulting competitive and/or noncompetitive substrate inhibition or an alteration of the protein conformation. An irreversible inhibition by covalent binding of the xenobiotic (or its derivatives) with functional, catalytic enzymatic groups may also occur

with deleterious effects on enzyme functions. Indirect effects are the consequence of possible xenobiotic-induced changes in size, structure, and functionality of the microbial community, in turn of the genesis and synthesis of new intra- and extracellular enzymes, and changes in the ratio between intra- and extracellular enzyme amounts.

These are the main reasons of the often contradictory results obtained on the influence of pesticides on soil enzyme activities (Schaffer, 1993; Gianfreda and Rao, 2008).

To address this aspect and evaluate the possible impact of pesticides on soil enzyme activities, Gianfreda and coworkers (Gianfreda et al., 1993b, 1994, 1995b, 2002; Sannino and Gianfreda, 2001) developed an experimental design that took into account the variability of soil enzyme categories. The effects of four pesticides, three herbicides (atrazine, paraquat, glyphosate), and one insecticide (carbaryl), on the activities of invertase (I), urease (U), and phosphatase (P) under different "states," were studied in the laboratory. The model systems, simulating enzymatic categories possibly occurring in soil, were (1) enzymes free in solution, to simulate enzymes free in soil solution; and (2) synthetic clay-, organo- and organo-clay-enzyme complexes, simulating soil-bound enzymes, and enzyme activities of whole soils, representing natural systems (Table 5.3). The synthetic enzymatic complexes were among those already discussed and presented in Section 5.3.3, that is, montmorillonite-bound enzymes (M-I, M-U, M-P), tannic acid-bound enzymes (T-I, T-U, T-P), and Al(OH)_x-tannic acid-montmorillonite-bound enzymes (ATM-I, ATM-U, ATM-P).

TABLE 5.3 Effect of Atrazine, Carbaryl, Glyphosate, and Paraquat (and Methanol Used as Solvent for Carbaryl and Atrazine Preparation) on the Activity of Free and Immobilized Enzymes

	Relative Activity ^a				
Enzymes	Glyphosate	Paraquat	Atrazine	Carbaryl	Methanol
Free enzymes					
Invertase (I)	1.80	1.23	0.71	0.53	0.64
Urease (U)	0.93	0.96	0.58	0.53	0.64
Phosphatase (P)	1.05	_	0.61	0.76	0.74
Immobilized enzyr	nes				
M-I	1.10	1.10	0.62	0.67	0.51
M-U	1.03	1.79	0.54	0.60	0.57

M, montmorillonite; T, tannic acid; ATM, OH-Al-tannic acid-montmorillonite.

^a The results are expressed as increments or decrements of the activities measured without pesticides (activity in the absence of pesticides = 1).

The results shown in Table 5.3 clearly indicate that the response of each enzyme to the presence of each pesticide was strongly influenced by the type of enzyme and its status, that is, if free or bound to inorganic, organic, or organo-mineral supports, and by the type of pesticide. For example, glyphosate had no effect on free phosphatase but severely depressed its activity (by about 20%–40%, with respect to the activity in the absence of pesticide) when the enzyme was immobilized on synthetic complexes (Table 5.3). By contrast, the same pesticide activated free invertase but had no effect on immobilized invertase. Varied results were also obtained with the other tested pesticides and methanol (the solvent in carbaryl and atrazine solutions) (Table 5.3).

Complex and not easily explainable responses were also obtained when the effects of the four pesticides on the three enzymes were investigated using several whole soils collected at different sites in Italy, which exhibited different physicochemical properties (Gianfreda et al., 1994; Gianfreda et al., 1995b; Sannino and Gianfreda, 2001). For example, in the presence of glyphosate the invertase activity of some soils increased between +4% and +204% and decreased by an average of 30% in other soils. Increases, decreases, or no changes were measured on soil urease activity with paraquat and glyphosate (Gianfreda et al., 1994). By contrast, inhibition by 50% on average was observed on the activity of phosphatase in all soils (Sannino and Gianfreda, 2001). As summarized by Gianfreda et al. (2002), some interpretations can be made by considering the substantial differences of the investigated systems. Indeed, the interaction between a pesticide and a free enzyme occurs in a homogeneous system, and direct interactions at the molecular level may occur. By contrast, with immobilized enzymes a heterogeneous system is present, and different interactions can occur not only between the immobilized enzyme and the pesticide but also between the support and the pesticide. Complex and also opposite effects may occur, all contributing to the measured response.

It is important to emphasize that tests conducted in the laboratory might not be ecologically interpreted. Contrary to model laboratory systems, pesticides in soil may be sorbed onto colloids, degraded rapidly, or exist in widely varying concentrations at different microsites. Therefore, the variability of the results previously mentioned suggests that no generalizable conclusions can be drawn, at least with the experimental systems under laboratory conditions.

The ability of extracellular enzymes in the transformation and degradation of pollutants and xenobiotics is backed by several findings (see reviews by Gianfreda and Bollag, 2002; Gianfreda and Rao, 2004). Oxidoreductases, released by both root or microbial cells, were effective in the transformation of several pollutants including polychlorinated biphenyls (PCBs), polycyclic aromatic hydrocarbons (PAHs), azo dyes, biopolymers (kraft, lignin), bleach plant effluents, chloroderivatives, phenol derivatives (like pentachlorophenol), and trinitrotoluen. Microbial hydrolases, such as esterases and depolymerases, were able to degrade highly recalcitrant and persistent materials such as plastics, including polyurethanes, polyacrylates, polylactides,

nylon, starch polymers, and mixed composites of different starting materials. These transformations, however, occurred very often in the presence of enzyme-producing cells, thus relying on the activity and functionality of their metabolism.

By contrast, the use of cell-free enzymes could have several advantages over the use of microbial cells because of their peculiar characteristics, such as higher reactivity and substrate specificity, and ability to function under a wide range of environmental conditions, which are often unfavorable to active microbial cells. They even function in the presence of toxic compounds and are not sensitive to predators or inhibitors of microbial metabolism (Nanniperi and Bollag, 1991; Karam and Nicell, 1997; Dick and Tabatabai, 1999; Gianfreda and Bollag, 2002; Gianfreda and Rao, 2004).

The most prevailing enzymes active as free enzymes in the transformation of pollutants are undoubtedly oxidative enzymes such as phenoloxidases (laccase, tyrosinase) and PODs (lignin and manganese PODs), which are often of fungal origin. These enzymes may be relatively nonspecific and have a very high redox potential. Consequently, they may be able to oxidize recalcitrant pollutants, which are not easily transformed by other enzyme-mediated reactions. For instance, several fungal laccases were tested for the removal of several pollutants from aqueous, solid, and hazardous wastes (Gianfreda et al., 1999 and references therein). Bollag (1992) proposed that laccases were suitable agents for the detoxification of polluted soils. He founded his assumption on the ability of laccase to reduce the toxicity of phenolic substances in the soil by their stabilization through incorporation in humic materials rather than by degradation.

Most of these results were, however, obtained under laboratory conditions, and few results are available on the real effectiveness of enzymes in soil environments. Moreover, the majority of results were obtained with free and unbound enzymes. When extracellular enzymes are applied for the detoxification of soils, their interaction with soil constituents may have two concomitant but contrasting effects on their efficiency in the removal of polluting substances. Their activity and catalytic power may be reduced, but their stability and reusability may be increased. Both processes are the consequence of their immobilization on soil supports.

An attempt to overcome this lack of knowledge was made by Ruggiero et al. (1989) and Gianfreda and Bollag (1994) who used laccase and POD free and immobilized on clays and soils and evaluated their ability to detoxify soils polluted by 2,4-dichlorophenol, a derivative of the pesticide 2,4-D, which is widespread in soils and sediment. Investigations were performed with soils differing in their chemical and physical properties. Besides some interesting properties shown by the immobilized enzymes (e.g., high residual activity and elevated stability to thermal denaturation, storage, and proteolytic attack) (see Section 5.3.3), both free and immobilized enzymes displayed catalytic activity in soil environments. Laccase and POD were able to remove up to 60% of the initial substrate concentration in the presence of soil, having a low content of OM. However, by increasing the OM

content, an inhibitory effect on the activity of free and immobilized enzymes was observed (Gianfreda and Bollag, 1994). Another important property of immobilized laccase and POD was that both enzymes retained their activity in the removal of 2,4-DCP for up to six incubation cycles. In the presence of soils, the inhibitory effect decreased after each incubation cycle, indicating that the observed inhibition was probably caused by soil-soluble components, which were easily extracted and removed when the substrate was replaced with a fresh buffered solution (Gianfreda and Bollag, 1994).

As summarized in Gianfreda and Rao (2004) and in Gianfreda et al. (2002), a completely different behavior was observed when laccase was not chemically linked to the support and acted in the reaction assay along with inorganic or organic soil colloids (single or in combination), soils, or sand, (Figure 5.4). In comparison with the control, that is, the enzyme alone, soil components differently affected the 2,4-DCP-laccase activity. When montmorillonite was present in the reaction mixture, less than 50% of activity was measured. A complete inhibition of the enzymatic activity was observed with AM₁₈ (Figure 5.4). No effects were evident with humic acids, but the effect of AM₁₈ dominated over that of humic acids when the two colloids were simultaneously present. Contrary to what was previously reported for laccase covalently bound to clays (e.g., preservation of high enzymatic activity levels), adsorption of enzymatic molecules on clay surfaces resulted in a concomitant loss of activity of the adsorbed enzyme. These results are in accordance with those previously described and further demonstrate that adsorption of enzymes on clays usually results in a significant decrease in activity of the adsorbed enzyme.

Reusability of enzymes is a necessary prerequisite for their use in practical applications for the restoration of polluted environments (Dick and Tabatabai, 1999). Enzymes covalently

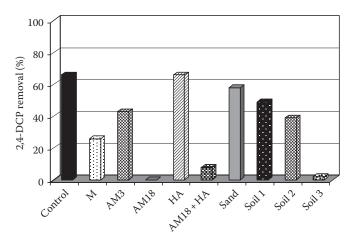

FIGURE 5.4 Removal of 2,4-DCP by laccase in the presence of clays, clay-humic complexes, sand, and soils. M = Na-montmorillonite; AM = montmorillonite covered by different amounts of OH-Al species (AM_3 and AM_{18} , loading 3 and 18 meq of Al g^{-1} clay), HA = humic acid. (From Gianfreda, L., and M.A. Rao. 2004. Potential of extra cellular enzymes in remediation of polluted soils: A review. Enz. Microb. Technol. 35:339–354. Copyright 2004, with permission of Elsevier.)

immobilized on solid supports may retain their activity much better than adsorbed enzymes as indicated by the investigations of Chang and Juang (2004, 2005, 2007) and Sanjay and Sugunan (2005, 2006, 2007).

5.6 Conclusions and Future Prospects

The findings reported and discussed in this Chapter provide strong experimental evidence not only of the importance of extracellular enzymes in soil but also of the impact of their interactions with soil components on their activity and stability. Both free and soil-bound enzymes may have significant effects on soil biology and biochemistry, microbial diversity, plant growth and nutrient uptake in ecosystems, and environmental management and restoration.

After interaction with inorganic, organic, and organomineral soil colloids, enzymes are usually not as catalytically active as enzymes that are free in aqueous solution, but they are frequently more stable to some environmental stresses such as extreme temperatures, digestion by proteases, and other severe conditions. These properties may vary between specific enzymes and confer on them the capability of performing a large variety of chemical reactions vital to soil fertility and soil health.

Several factors may affect the behavior of enzymes immobilized on soil colloids (Nanniperi and Gianfreda, 1998): (1) Changes in the conformation of enzymatic proteins, due to denaturing effects of the supports or of interactions between the enzyme and the support, very often pH dependent; (2) Steric hindrances to the access of substrate to the active center of the enzyme, much more marked with high molecular mass substrates; (3) Microenvironmental effects due to the different local microenvironment, surrounding the enzyme linked to the support, and strongly dependent on its chemical nature; (4) Perturbation of the protein conformation due to combination of electrostatic and hydrophobic forces and pH dependence; (5) Diffusional limitations, since the rate of transformation by immobilized enzymes is influenced by the availability of the substrate and the effectors. Considerable changes in the values of kinetic parameters can be expected, and those observed are only "apparent."

Soil-bound enzymes also have a great potential in maintaining soil biodiversity and assuring a correct and integrated balance between input, assimilation, and utilization of major nutrients and output of inorganic derivatives contributing to greenhouse gases with consequences on global climate changes. They are not sensitive to induction-repression phenomena that usually regulate the production of extracellular enzymes by microorganisms, have a longer turnover time than that of free extracellular enzymes, and therefore represent a stable pool of potential enzyme activity of soil to also function in the absence of living organisms.

Soil-bound enzymes may mediate the transformation and degradation of pollutants, but their reduced catalytic activity can be an obstacle to an effective restoration of polluted soils. On the other hand, their increased stability and the possible involvement of the soil support in the pollutant transformation

(i.e., adsorption of either substrates or released products, direct participation to pollutant degradation [Huang, 1990, 1995; Ruggiero et al., 1996; Naidja et al., 2000]) may enhance their performance and provide soil with a persistent, active pollutant degradative capability. Their effective use in soils for environmental cleanup or for modifying biochemical activities still requires, however, an exhaustive understanding of the influence of the soil microenvironment.

Advances in the knowledge of production, regulation, and stabilization of soil enzymes, and in particular of the formation and performance of soil-bound enzymes, of their involvement in the transformation of nutrients, degradation of pollutant, and functioning of soil at a global level, will derive if suitable methodologies are available for (a) measuring and modeling in situ activity of soil enzymes, (b) determining the fraction of stabilized enzymes and their activity, (c) defining the exact mechanisms occurring in vivo in the interactions between enzymes and inorganic and organic soil colloids, (d) determining surface structures of the enzyme–soil colloid complexes, (e) distinguishing the contribution of abiotic reactions to the transformation of nutrients and/or pollutants, and (f) elucidating the concomitant action, if any, of more than one enzyme bound to the same support, in case this occurs.

As reviewed by Wallenstein and Weintraub (2008), emerging tools, including genomic, proteomic, and metabolic tools, are now available for achieving most of the cited needs and for improving "understanding of the drivers of in situ enzyme activities." Genomic studies will assist in elucidating the production of enzymes in soil and the regulating factors. An increased capability for modeling and predicting enzyme pools under different conditions will result. Proteomic studies will provide information on the diversity and source of extracellular enzymes in soil. They will help in discovering and characterizing the production of novel extracellular enzymes independently of assays based on substrate transformation. Imaging methodologies will allow a direct measurement of in situ enzyme activity, thus contributing to a full understanding of the complex interactions between microbial cells, enzymes and clay minerals, or OM. Notwithstanding the fundamental contribution to the visualization of soil microenvironments provided by the studies of Forster and coworkers (Ladd et al., 1996), who developed imaging methodologies to identify the "in situ" activity of several soil enzymes, some limitations are still present in their application. Metabolomics will be useful to quantify the products of enzyme-mediated degradation or transformation of substrates and pollutants and indirectly to evaluate the production and activity of soil enzymes.

Moreover, advanced analytical instrumentation such as atomic force microscopy, scanning tunneling and infrared spectroscopy, and synchrotron-based x-ray spectroscopy will be helpful to clarify the interactions occurring at the molecular level between enzymes, clays, and OM; their catalytic involvement in the transformation of nutrients and pollutants; and their contribution to the whole soil enzyme activity.

The combination and integration of updated information achieved by these methodologies will contribute to reach the goals and objective of the Commission 2.5—Soil, Physical, Chemical and Biological Interfacial Reactions of the International Union of Soil Sciences, that is, "advancing the understanding on physical/chemical/biological interfacial systems at the molecular to field/landscape levels."

6.1 Introduction

The rhizosphere is defined as the zone of high biological and chemical activity in the soil that surrounds the living root (e.g., Curl and Truelove, 1986; Pinton et al., 2007; Dessaux et al., 2010). The rhizosphere is chemically, physically, and biologically different from the bulk soil because it has been modified by roots and the associated microorganisms (Table 6.1). Detailed knowledge of the processes in the rhizosphere is fundamental to understanding the interactions of plants with their environment and the development of sustainable agricultural and forestry production systems. Similarly, the rhizosphere is important for many other environmental issues including biosphere C sequestration, greenhouse gas mitigation, human pathogen transfer in the food chain, and the removal, stabilization, and transformation of pollutants in soil (Huang and Gobran, 2004; Cardon and Whitbeck, 2007; Hinsinger et al., 2009; Philippot et al., 2009b). Despite its importance in many ecosystem services, our understanding of the rhizosphere remains relatively poor (Dessaux et al., 2009, 2010). This is due to the intrinsic complexity of the rhizosphere where many thousands of linked processes are operating simultaneously in a highly heterogeneous soil matrix. Unraveling this complexity is a long-term scientific goal that will not be fully realized within our lifetime. Ultimately, however, understanding these processes will allow managing the rhizosphere to harness its natural potential for the sustainable management of ecosystems (Ryan et al., 2009; Wenzel, 2009; Dessaux et al., 2010).

The dimensions of the rhizosphere vary greatly depending upon how it is defined. For example, gaseous chemicals released from roots (e.g., signaling molecules) are known to travel many meters in soil, and theoretically this zone of influence could be termed the rhizosphere. In addition, if one considers mycorrhiza, then the mycorrhizosphere may also greatly extend the root's sphere of influence, while the high root density in grasslands means that all the soil can be considered as rhizosphere. To most scientists, however, the rhizosphere encompasses the zone 1–2 mm away from the root surface where maximum microbial activity occurs and where the greatest changes in soil chemistry and physics are apparent (Jensen et al., 2005; Raynaud, 2010). The rhizosphere also extends into the root, the endorhizosphere; numerous studies have shown that symbiotic and nonsymbiotic bacteria and fungi colonize the cortex of the root (Vanpeer et al., 1990; Roesti et al., 2006; Figure 6.1). One of the key features is that every point in the rhizosphere is chemically, physically, and biologically unique because of the simultaneous influx into and efflux of chemicals from the root (e.g., inorganic nutrients, water, H+, organic compounds), which results in unique diffusion gradient profiles in the soil (Figure 6.2). In addition to these root-induced gradients, rhizosphere processes are also highly

TABLE 6.1 Biophysical, Biochemical, Biogeochemical, and Biological Properties of the Rhizosphere

Root/Rhizosphere Microorganism Biological Function	Soil/Rhizosphere Property	Soil/Rhizosphere Process
Root growth/elongation	Bulk density/porosity	Fluid (water, gas) transfer (convection, diffusion)
	Soil strength	•
	Soil structure	
Mucilage/exopolysaccharide	Viscosity	Adhesion of particles
production/secretion	Surface tension	Aggregation
		Water/solute transfer
Water uptake (by roots)	Water content/tension	Water flow (along water tension gradient)/gas transfer

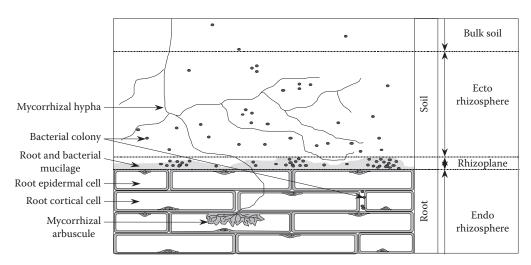

FIGURE 6.1 Schematic representation of an endomycorrhizal root showing the different parts of the rhizosphere.

variable along the root length in response to differences in root morphology (e.g., root hair zone versus lateral root emergence zone), differential exploitation of soil resources (e.g., water, P depletion), changes in the soil atmosphere (e.g., O₂, CO₂), and aging of the rhizosphere microbial community (e.g., in response to a reduction in the quality and quantity of root organic C flow into the soil). Together this spatial heterogeneity makes it extremely difficult to generalize rhizosphere processes occurring on the root system of a single plantlet alone to plants growing

in different soil types or regions. This also makes it difficult to devise rhizosphere management techniques that are acceptable to industry and are generally applicable across wide geographical areas. This review aims to summarize current knowledge in the area of biogeochemical, biophysical, and biological processes occurring in the rhizosphere. Due to the number of published works in this area (>15,000), it is impossible to summarize every aspect of the rhizosphere; here we can all but provide an overview of the most important processes (see also Table 6.1).

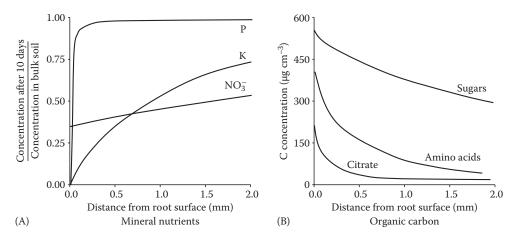

FIGURE 6.2 Schematic representation of the gradients in (A) mineral nutrients and (B) root exuded carbon in the rhizosphere, which makes every point in the rhizosphere chemically unique.

6.2 Rhizosphere Biochemistry

6.2.1 Exudation and Secretion of Organic Compounds

The biological and chemical processes operating in the soil surrounding the root can be dramatically different from those occurring in the bulk soil due to the many interactions occurring between roots, microorganisms, and soil particles. One of the main driving forces in changing the chemical, biological, and physical properties of the soil is the release of organic compounds (Pinton et al., 2007) by the root into the soil (termed root exudation or rhizodeposition (Nguyen, 2003; Jones et al., 2009). Indeed, this release of C provides the energy for microbial proliferation in the rhizosphere (Figure 6.1). Despite the central importance of C flow in rhizosphere processes, our knowledge of the subject still remains fragmentary and limited to a few well-studied examples, typically young crop plants studied ex situ. To a large extent, this is due to the intrinsic difficulties in studying rhizosphere C flow in situ at sufficient spatial resolution to draw valid conclusions. Although we have a range of isotopic forms of C at our disposal for tracing C in the plant-soil system (i.e., 11C, 13C, 14C), our ability to use them effectively has often been limited by the inability to physically separate roots from soil and the lack of high resolution in situ imaging techniques. As a result of the lack of suitable techniques, the rhizodeposition literature contains many studies that have employed inappropriate methodology and from which erroneous conclusions have subsequently been drawn.

Despite experimental limitations, numerous isotopic tracer studies have quantified the amount of C fixed in photosynthesis that is subsequently partitioned belowground and then lost via exudation. Although there are numerous caveats in the interpretation of the results (Meharg, 1994; Nguyen, 2003; Thornton et al., 2004; Paterson et al., 2005), a meta-analysis of 271 studies undertaken by Jones et al. (2009) has revealed some consensus in C partitioning over a wide range of plant species and experimental conditions. Overall, it appears that when plants are fed with isotopically labeled $^{13}\mathrm{CO}_2$ or $^{14}\mathrm{CO}_2$, approximately 60% \pm 10% of

the fixed C (range 20%-98%) remains in the shoot, becoming incorporated into new growth and storage pools. The remaining $40\% \pm 10\%$ is transferred belowground to the root system. Within the root, the newly fixed C has a number of fates including the transfer to new growing tips and symbionts (e.g., N2 fixers, mycorrhizal fungi), the repair of older tissues, and loss in respiration or loss into the soil as gaseous, soluble, and insoluble exudates. Once in the soil, the released C can then undergo a number of fates including diffusion away from the root, uptake and respiration by soil microorganisms, uptake and incorporation into new microbial cells, abiotic sorption to soil particles, abiotic mineralization by mineral oxides, leaching through the soil, volatilization from the soil surface, and recapture by the root itself or by neighboring roots (Figure 6.3; Martin, 1970; Jones and Darrah, 1994; Kuzyakov et al., 2003; Paterson et al., 2007; Jones et al., 2009). Separating these numerous fluxes, which occur concurrently and which possess many interrelated feedback loops, has proved impossible, and this has limited a holistic understanding of C flow and the importance of individual processes. On balance, it appears that of the C that is transferred belowground, approximately 19% ± 8% remains in the root (range 5%-55%), $5\% \pm 1\%$ is lost from the root and incorporated into soil organic matter (SOM) (range 2%-18%), and 12 ± 5 is lost as CO₂ (Jones et al., 2009). This respiratory loss arises from roots and from the microbial turnover of root exudates (range 2%-30%). Distinguishing between root and microbial respiration has been one of the major constraints to gaining an accurate measure of rhizodeposition in soil-grown plants. Using a range of experimental approaches, it is now believed that roots and microorganisms contribute equally to rhizosphere respiration (Kuzyakov, 2002a, 2006), an assumption that must be considered with caution. Carbon loss by rhizodeposition has therefore been estimated to be around 11% of the net fixed C or 27% of C allocated to roots, which corresponds to 0.4-0.6 Mg C ha-1 year-1 in cereals (Kuzyakov and Domanski, 2000). This can be compared to the average organic C content of a typical agricultural topsoil (0-30 cm) of 50 to 150 Mg C ha-1.

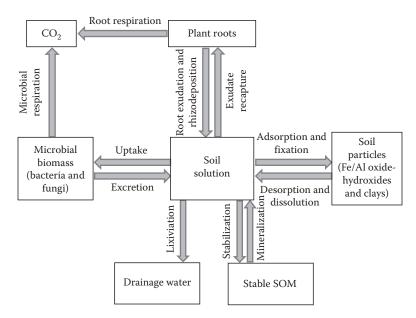

FIGURE 6.3 Schematic representation of the major pools and fluxes of root-exuded carbon in the rhizosphere. SOM indicates soil organic matter.

Typically, it takes minutes for the C fixed in the shoots to start being transferred belowground (Dilkes et al., 2004) and then only a few more minutes before the C is unloaded from the vascular bundle and enters the root metabolism. As root metabolic activity is closely linked to photosynthetic flux (Todorovic et al., 1999; Kuzyakov and Cheng, 2004; Hill et al., 2007), root exudation is very sensitive to C supply although some buffering does exist due to C storage in roots (e.g., as starch). This storage pool has the potential to buffer cytoplasmic metabolism for about 1–3 days if C supply from the shoots is cut off (Saglio and Pradet, 1980). Consequently, exudation into the soil varies dramatically depending upon the physiological state of the plant and the prevailing environmental conditions (Nguyen, 2003).

The composition of root exudates has largely been investigated in sterile hydroponic culture in the absence of soil to prevent loss of exudates by microbial decomposition and to facilitate their collection for analysis (Curl and Truelove, 1986). Virtually all compounds contained in root tissues can be released as root exudates including carbohydrates, organic and amino acids, peptides, phenolics, fatty acids, sterols, and proteins, including enzymes, vitamins, hormones, and nucleosides. Pioneering work in the 1960s and 1970s explored the impact of numerous plant and environmental factors on the amount and composition of root exudates. All studies showed that any change in experimental conditions or ontogenetic stage of the plant resulted in differing net release rates of C and that in each case, the plants produced a unique chemical exudation signature (Vancura, 1967; Rovira, 1969; Vancura and Stotzky, 1976). This has made it very difficult to generalize about the exudation process and its contribution to ecosystem C budgets. Further, it has also been found that exudation is not spatially uniform but varies both along the root length and with root age (McDougal and Rovira, 1970). Generally, rates of exudation are greater at growing root tips in comparison to mature root regions (Hoffland et al., 1989;

Ryan et al., 2001; Shane and Lambers, 2005). Reasons for this higher efflux at the tip include preferential site for apoplastic unloading of solutes, higher solute concentrations in the cells, smaller vacuolar volumes, greater surface area of tip cells due to their smaller size, the lack of an endo- or exodermal layer, higher internal C turnover rates, and tips being a major site of plasma membrane vesicle fusion (Jones and Darrah, 1996; Jones et al., 2009). Emergence points for secondary roots can also lead to hotspots of C loss (McDougal and Rovira, 1970). However, some signaling molecules also show a highly targeted release (e.g., flavonoids in the root hair zone released as a chemoattractant for N₂ fixing Rhizobium bacteria; Vanrhijn and Vanderleyden, 1995). It should also be noted that while the discussion above is predominantly associated with C loss, root exudation is also synonymous with N loss (e.g., in the form of amino acids, peptides, and proteins).

It is well established that the release of insoluble polysaccharide gel (mucilage) is predominantly associated with root tips and due to secretion by root cap cells (Figure 6.4; Paull and Jones, 1975a, 1975b, 1976a, 1976b). This gel plays a number of roles in enhancing plant growth including (1) reducing frictional resistance at the root tip and thus preventing abrasive damage from soil particles (although this has been debated, e.g., in Read et al., 1999), (2) complexation and detoxification of toxic metals (e.g., Al, Cd, Pb), preventing inhibition of the actively growing root meristem, (3) buffering the pH around the root apex, and (4) promoting aggregate stability and soilroot contact, thereby facilitating water and nutrient transfer toward the root (Horst et al., 1982; Traore et al., 2000; Knee et al., 2001). In recent years, it has become apparent that the release of border cells at the root apex may also play an important role in regulating a range of rhizosphere processes (Hawes et al., 1998). Border cells are cells that are continually sloughed off from the root apex cells in a controlled manner. After their

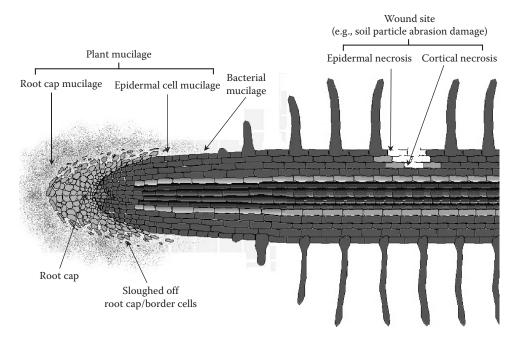

FIGURE 6.4 Schematic representation of the main sites of mucilage production along a root.

release from the root, they can survive for several days in the soil but eventually die, providing a substrate for microbial growth. Although they only represent a small C loss to the plant (0.1%–5% of rhizodeposition depending upon plant species), their role appears to be similar to that of mucilage in that they (1) reduce the frictional force experienced by the root tip (Iijima et al., 2003), (2) bind and keep aluminum and heavy metals away from the root (Horst et al., 1982; Llugany et al., 2003), (3) produce signal compounds that deter plant pathogens (e.g., nematodes and fungi; Hawes et al., 2000), and (4) release signals that attract potential symbionts (Brigham et al., 1995; Hawes et al., 1998; Nagahashi and Douds, 2004).

Until the 1990s it was generally accepted that the release of soluble C exudates from roots was purely a passive process whereby C compounds were simply lost in response to the large concentration gradient that exists between the root (solute concentrations within cells of 1-50 mM) and the soil solution (0.1–50 $\mu M).$ However, we now know that this is a gross oversimplification of the process, casting doubt on many of the conclusions drawn from earlier studies. This arose as we gained a deeper understanding of the membrane transport processes involved in exudation and specifically that (1) plants can tightly regulate the spatial and temporal release of some compounds (e.g., organic acids, signaling compounds) and (2) that plants can recapture exudates from the soil (Jones et al., 2009). One key question that remains unanswered is why plant roots take up C compounds from soil? Current theories include that it allows (1) capture of C compounds that are delivered apoplastically to root cells (e.g., at growing tips), (2) that direct recapture of exudates is used to enhance the plant's C efficiency and to reduce rhizosphere microbial growth and pathogen attack, (3) direct uptake of C and N compounds allowing the capture of organic nutrients

released from SOM, and (4) that uptake provides a mechanism for inter-root and root–microbial signal exchange.

Of greatest ecological significance is the active root uptake of sugars and organic N compounds (e.g., amino acids and polyamines) from soil. Typically, these compounds are taken up into the root cells by cotransporters, which are constitutively expressed and located throughout the root system (Jones and Darrah, 1994, 1996; Figure 6.3). These cotransporters are powered by the plasma membrane H⁺-ATPases, which are predominantly located in the epidermis rather than in the root cortex, although levels of H⁺-ATPases are also high in the stellar regions (Samuels et al., 1992; Jahn et al., 1998). The transport proteins simultaneously transport H⁺ across the plasma membrane into the cells together with individual organic solutes. The transporters are also relatively solute specific, with transport families for amino acids and sugars being nowadays well characterized at both the physiological and molecular level (Hirner et al., 2006).

6.2.2 Organic Nutrient Mobilization: Enzymatic Processes and the Fate of C, N, P, and S

6.2.2.1 Uptake of Soluble Organic Nutrients

As highlighted above, plant roots have the potential to actively take up low molecular weight (MW) organic compounds from the apoplast and from outside the root (e.g., amino acids, sugars, urea; Phillips et al., 2004; Personeni et al., 2007). From a limited number of studies, it appears that this trait is constitutively expressed and occurs along the entire length of the root and in all root types (Jones and Darrah, 1994, 1996). Although some root uptake can occur purely by passive diffusion down the

electrochemical potential gradient across the plasma membrane, these diffusive flux rates appear to be low and largely limited to neutrally charged solutes in a protonated form (e.g., H-acetate⁰) rather than in a metal-complexed form (e.g., Al-citrate⁰; Jones and Darrah, 1995; Ogiyama et al., 2010). The main proportion of root uptake of amino acids and sugars is mediated by proton cotransporters, which are driven by H+-ATPases. There is evidence that roots may possess multiple transport systems capable of high and low affinity transport to enable the root to respond to a wide range of external concentrations (Xia and Saglio, 1988). In addition, the transporters may be upregulated under extreme anoxia (Gharbi et al., 2009). The ecological significance of this uptake pathway, however, remains controversial. Initially, it was considered that the uptake of low MW solutes from soil was a way for the root to recapture C lost in exudation to the soil or from the apoplast when C is unloaded from vascular tissues (Jones and Darrah, 1994, 1996). However, a different but complementary theory is that transporters are present to enable roots to take up sugars and amino acids released during the microbial breakdown of organic matter in the soil. This could supplement the plant's supply of C and particularly N. In the case of amino acid uptake, it would bypass the need to wait for amino acid mineralization into NH₄ and NO₃ by the soil microbial biomass (i.e., short-circuiting the N cycle). Although there is evidence to support the importance of this N uptake pathway in N limiting ecosystems (e.g., Arctic tundra and boreal forest; Chapin et al., 1993; Lipson and Nashölm, 2001; Nashölm et al., 2009), it appears to be of less importance in temperate and tropical environments (Owen and Jones, 2001; Kuzyakov and Jones, 2006). Further, the methodology for determining the uptake of isotopically labeled (13C/15N) organic solutes has drawn considerable criticism in recent years due to a lack of consideration for isotopic pool dilution, transformation of labeled compounds in soil, use of inappropriate tracer concentrations and experimental times, and difficulties in separating microbial and root uptake and mineralization (Jones et al., 2005; Rasmussen and Kuzyakov, 2009). A special case are phytosiderophores in Poaceae; these plant species have evolved transport systems to take up Fe and Zn, as well as other micronutrients such as Mn and Cu, once chelated by phytosiderophores (i.e., in the metal-complexed form), which are nonproteinogenic amino acid derivatives released by Poaceae roots (Marschner, 1995; Robin et al., 2008).

6.2.2.2 Enzymatic Processes in the Rhizosphere

Typically, key nutrients such as N, P, and S are locked up in insoluble organic matter in most soils. Consequently, for plants to access this nutrient pool SOM is enzymatically broken down into low MW soluble compounds and further into inorganic ions to be transported across the root plasma membrane. In most soils, this breakdown process can occur in the absence of plants by soil microorganisms with the aid of micro-, meso-, and macrofauna. However, the fact that microbial activity is higher in the rhizosphere than in nonrhizosphere soil has led to speculation that enzymatic turnover of SOM might be enhanced around the root (i.e., the rhizosphere priming effect; Ahmad and Baker, 1987;

Kuzyakov, 2002b; Vong et al., 2003). This is supported by studies showing that root C inputs stimulate the mineralization of organic pollutants and SOM, which in theory should concomitantly release inorganic nutrients (Gerhardt et al., 2009). In addition, roots are known to release a range of enzymes involved in the breakdown of organic matter. In contrast, more recent studies have indicated a more complex picture where it is difficult to disentangle enzyme-mediated nutrient mobilization of SOM from that associated with enhanced rates of microbial biomass turnover (Weintraub et al., 2007). Irrespective of the source, there is no doubt that enzymatic activity is enhanced around the root. To date most functional enzyme work has focused on P mobilization and to a lesser extent N mobilization with scant attention paid to other nutrients (e.g., Fe, S). In the case of phosphatase, the observation that exudation of acid phosphatase from cluster roots of white lupin coincides with increased exudation of organic acids suggests that plants have coordinated adaptive strategies to maximize their potential synergistic effects under P-deficient conditions (Gilbert et al., 1999). Although efforts have been made to genetically engineer plants to release higher amounts of enzymes into the soil (e.g., phytase), these have so far proved unsuccessful at promoting plant P acquisition in situ (George et al., 2005). However, it is likely that roots will be engineered to release a range of enzymes, particularly in nonmycorrhizal crop plants.

In many instances, the organisms involved in SOM breakdown may also be symbiotically associated with roots, implying a direct connection between the site of breakdown and transfer directly to the root in exchange for C (e.g., mycorrhizas). Indeed, there are many studies showing higher rates of phosphatase activity in soil surrounding mycorrhizal roots and enhanced P and N transfer to the plant (Bolan, 1991; Leake and Read, 1991; Tarafdar and Marschner, 1994; Perez-Moreno and Read, 2000). In these experiments, it is often difficult to distinguish between enzymes released from the root and those from the mycorrhizal fungi. Typically, phosphatases released from fungi are able to mineralize a greater range of organic P forms and at a higher rate than those released from roots (Tarafdar et al., 2001). The magnitude of this response appears to be highly dependent upon both soil type and plant genotype but more importantly, the type of mycorrhizal fungal species (Tadano and Sakai, 1991; Joner and Johansen, 2000; van Aarle and Plassard, 2010). Responses may also be controlled by the composition of the rhizosphere microbial community with whom the mycorrhizal fungi are competing (Baum and Hrynkiewicz, 2006; Phillips and Fahey, 2006).

Mycorrhizas can release a wide range of enzymes involved in SOM breakdown (e.g., proteases, laccases, phenol oxidase, sulfatases, urease, chitinase, acid, and alkaline phosphatase), and many show an upregulated release pattern under nutrient limitation (Vazquez et al., 2000; Raiesi and Ghollarata, 2006). The increase in enzyme activity appears to be associated with the extraradical hyphae away from the root (i.e., the scavenging growth front rather than by hyphae at the root surface; Huang et al., 2009). Ectomycorrhizas may stimulate the dissolution of mineral P and mobilization of soil organic P simultaneously (Liu et al., 2005).

However, it should be noted that it is often difficult to differentiate between cause and effect in many nonfactorial experiments, particularly those involving arbuscular mycorrhizas that cannot be studied in the absence of the host (Kang and Freeman, 2007; Bai et al., 2009). This is particularly true where symbionts enhance plant growth by another mechanism (e.g., making roots less susceptible to H⁺, Al³⁺, or metal toxicity), which in turn affects root–shoot resource partitioning, plant nutrient demand, and microbial community structure in the rhizosphere, all of which can affect enzyme release (Kohler et al., 2007).

6.3 Rhizosphere Biophysics

6.3.1 Porosity Development, Aggregation, and Compaction

The soil matrix is responsible for considerable biophysical constraints on soil living organisms, as related to soil strength, and the distribution/availability of gas and water. These constraints are also faced by roots of higher plants (Bengough et al., 2006); consequently, they have evolved a number of strategies to avoid or minimize these biophysical stresses. Roots of higher plants grow in soil pores, either by (1) using preexisting macropores such as cracks and biopores or (2) building new biopores. In most instances, root growth induces a substantial reorganization of the soil matrix, via aggregation and compaction processes, and thus, higher plants strongly influence the physical structure of soils (Hinsinger et al., 2009).

At the whole plant scale, the spatial extension of the rhizosphere will ultimately depend on (1) the architecture of the root system, which is to a large extent genetically determined (Lichtenegger and Kutschera-Mitter, 1991; Zobel, 1991), and (2) root growth and development, which rely on the allocation of C and environmental factors, either biological, chemical, or physical (Robinson, 1994; Hodge et al., 2009). The plasticity of the root system is indeed quite remarkable, showing the ability of plants to tolerate and respond to adverse soil conditions. A meta-analysis of 475 soil profiles from 209 geographic locations revealed that more than 90% of the soil profiles had at least 50% of their root biomass within the top 30 cm, and that 95% of all roots were in the upper 2m (Schenk and Jackson, 2002). However, these authors stressed that due to the technical difficulty to acquire quantitative data for large plants grown under field conditions, the extent of the root system may have been underestimated, particularly roots in the subsoil. There are a number of reports showing that many tree species have taproots growing to several tens of meters in depth, particularly in areas where water supply is limited (Canadell et al., 1996). Even fine roots can develop to a considerable depth in fast growing trees such as when growing in nutrient-poor soils (Jourdan et al., 2008). In Congo, Bouillet et al. (2002) showed that the distribution of fine roots of *Eucalyptus grandis* was quite homogeneous throughout the soil profile down to a depth of at least 3 m. Although plant roots growing in the upper horizon

encounter rather favorable physical conditions (low bulk density, high organic matter content, and oxygen supply), deeper roots will have to grow through a soil material that is, often, densely packed and waterlogged at least for some time of the year or contains an increasing density of large rock fragments. The use of computer-assisted tomography has recently helped making major steps forward for estimating to what extent plant species can reuse preexisting macropores, particularly to find their way through hard pans at depth (Jassogne et al., 2007; Jassogne, 2008). These studies showed that a large proportion of roots tend to make use of the preexisting macropores where they encounter minimal soil strength, which is in line with previous studies by Stirzaker et al. (1996), Stewart et al. (1999), and Lesturgez et al. (2004). Additionally, some species create their own root macropores more efficiently than others, for example, tap-rooted, perennial legumes such as Stylosanthes hamata (Lesturgez et al., 2004), lucerne, and saltbush (Atriplex nummularia), a native species of Australia (Jassogne, 2008). However, most plant species will use existing pores, as shown by Williams and Weil (2004) with minirhizotron images of soybean roots growing along channels left by decomposing roots of canola in a compacted soil. In similarly dense soils, Watt et al. (2005) showed that more than half of the entire length of the root system of wheat was in pores formerly occupied by roots. Biopores such as earthworm burrows and root channels, that is, either recent or relic rhizospheres, not only represent areas of lower soil strength and greater aeration but may also favor root growth because they are nutrient-enriched zones with distinct chemical and microbiological properties (Pierret et al., 1999, 2007).

The soil strength around the root apex greatly influences the pressure that a root must exert to penetrate the soil. In the absence of preexisting macropores, a root must exert sufficient pressure to rearrange the soil particles, that is, to push them either aside or ahead of the root apex. The mechanical stress in the soil around the growing root is likely to be greatest in front of the root apex. Kirby and Bengough (2002) modeled that an increase in root diameter decreased the peak axial stress in front of the root tip to facilitate root penetration. Root-induced changes in the rhizosphere bulk density (and thus porosity) will thus be maximal where roots exert most mechanical stress on the surrounding soil, that is, at the root tip. Young (1998) reviewed the variations of soil geometry from rhizosphere to bulk soil and showed a small but significant body of work reporting increased bulk density close to the root-soil interface. Such root-induced changes of soil physical properties can be substantial. Bruand et al. (1996) reported bulk densities as great as 1.8 g cm⁻³ next to the surface of maize roots, as compared with 1.5 g cm⁻³ in the bulk soil. Soil porosity was shown to decrease almost exponentially away from the root surface (Dexter, 1987). Higher soil density around the root results in increased root-soil contact and thus increased hydraulic contact, which can increase the accessibility to soil resources. However, in front of the root tip any increase in bulk soil density could inhibit root growth, as stressed by Hinsinger et al. (2009).

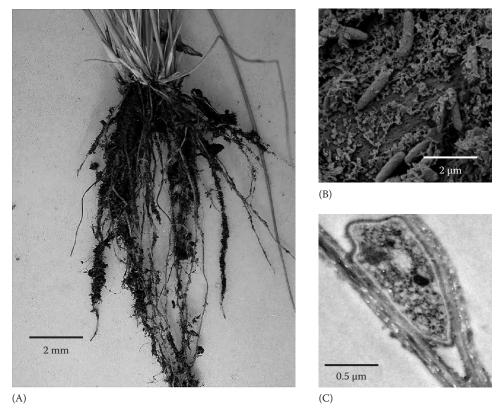

FIGURE 6.5 Photographs illustrating (A) soil adhering to the root of a *Poaceae* species (i.e., soil rhizosheaths), (B) an SEM image showing rod-shaped bacteria colonizing the root surface of a wheat (*Triticum aestivum*) root, and (C) a TEM image of an endophytic rhizobacteria living between two cells in the root cortex.

Conversely, Martens and Frankenberger (1992) and Alami et al. (2000) showed a significant increase in porosity in the rhizosphere, which was presumably related to exopolysaccharides produced by rhizobacteria altering soil structure in the rhizosphere. Kaci et al. (2005) reported that exopolysaccharides produced by Rhizobium had properties that could increase soil aggregation. Besides microbial exopolysaccharides, as stressed above, polysaccharides are also released from roots, the so-called mucilages, that considerably affect rhizosphere biophysics and, thus, structure-dependent processes such as water transport (Czarnes et al., 2000). The combined effect of root hairs and exopolysaccharides produced by root and rhizosphere microorganisms (Watt et al., 1993) can lead to the formation of so-called rhizosheaths (Figure 6.5), which have been shown in a wide range of plant species and particularly grasses (Watt et al., 1994; Young, 1995; North and Nobel, 1997; McCully, 1999; Moreno-Espindola et al., 2007; Hinsinger et al., 2009). Rhizosheaths are remarkably stable and can either facilitate or restrict soil-root water transfer (Watt et al., 1994; Young, 1995). Wetting and drying cycles, which result from the diurnal pattern of water uptake of a growing plant, are likely to play a major role in maintaining the soil stability in the rhizosphere (Hinsinger et al., 2009). However, the factors influencing soil stability in the rhizosphere are largely unknown. This

research area has received little attention, compared to rhizo-sphere biogeochemistry and biology.

6.3.2 Water and Nutrient Transport Processes

Besides anchoring the plants in the soil, the major role of the root system is to provide access to soil resources such as water and nutrients. Water uptake in the soil-plant-atmosphere continuum is a passive water flux driven by water potential gradients, with the root system providing the hydraulic continuity between the soil and the atmosphere, thereby playing a key role in the global water cycle (Hinsinger et al., 2009). The uptake of water by roots results in gradients in soil water content radially around a root if soil hydraulic conductivity becomes limiting for uptake as demonstrated experimentally by Hainsworth and Aylmore (1989) and Hamza and Aylmore (1992) and modeled by Doussan et al. (2003). Such gradients in soil water content or soil matric potential need to be taken into account in modeling plant water uptake. Doussan et al. (2006) combined models describing the architecture of the whole root system with a microscopic approach of describing water uptake based on potential gradients in soil-plant-atmosphere continuum and were able to reproduce the water distribution patterns obtained in experiments with crop species.

Hydraulic resistance during the axial transport of water is a key factor for water uptake by plants. The diurnal fluctuation in root diameter is a well-known phenomenon (e.g., Huck et al., 1970). It may give rise to large changes in root-soil contact (Van Noordwijk et al., 1993) and thus in hydraulic resistance of the root-soil interface. Exopolysaccharides produced by roots and microbes in the rhizosphere are considered to be important for retention and transport of water at the soil-root interface and in maintaining adequate soil-root contact as soils dry. Read et al. (1999) measured that maize mucilage may contain 99.9% water under dry conditions. Under wet conditions, McCully and Boyer (1997) showed that mucilage was able to retain even greater amounts of water than under dry conditions, that is, a typical gel behavior. Read et al. (2003) reported that surfactants in root mucilage, such as lecithin, may change the water-release properties within the rhizosphere, such that more water is released, particularly from relatively wet coarse textured soils. Whalley et al. (2005) showed for barley and maize that the rhizosphere was drier than the bulk soil at the same matric potential, partly as a result of changes in pore-size distribution and angle of wetting in the rhizosphere. On the other hand, hydrophobic compounds can also be produced in the rhizosphere, resulting in increased water repellency relative to bulk soil (Czarnes et al., 2000; Hallett et al., 2003). This further complicates the overall biophysical behavior of the rhizosphere.

As pointed out earlier, root distribution throughout the soil profile varies with season, plant development, and plant species, exhibiting a large plasticity to adapt to environmental conditions and especially to fluctuating availability of water and other soil resources in the various soil horizons (Callaway et al., 2003). When the topsoil dries, deeper roots may take up water from the ground water or soil layers close to it. In addition, roots may redistribute some water from wetter soil regions deeper in the soil profile to drier regions at the top of the soil profile. This socalled hydraulic lift occurs when water is released from roots when transpiration ceases (e.g., at night) and soil water potential in the dry soil becomes more negative than plant water potential. The amount of water transferred by hydraulic lift per night can range from 14% to 30% of daily evapotranspiration. Besides its role in water use efficiency, facilitation, or competition, this process may, more importantly, play a major role in nutrient uptake from dry topsoil and maintenance of root functions (Caldwell et al., 1998; Callaway et al., 2003; Newman et al., 2006).

Plant roots take up inorganic nutrients mainly as dissolved ions in the soil solution. Only a minor fraction of nutrients in the soil solution occur in the immediate vicinity of roots. Thus, nutrient interception is expected to contribute marginally to the overall acquisition of most nutrients by plants. Barber (1995) estimated for maize that interception was amounting to less than 2% of plant's requirement for major nutrients such as N, K, and P. In comparison, the uptake of water by roots, and the resulting gradient of water potential, is the driving force for a convective flow of dissolved nutrients toward the root's surface, often referred to as mass flow, which can supply a large

proportion of plant nutrient requirements. For those nutrients that occur at high concentrations in the soil solution, for example, nitrate in many soils, mass flow can contribute a major proportion of the amount of N taken up by plants, about 80% for maize as estimated by Barber (1995). For some cations such as Ca and Mg, mass flow can even exceed plant demand, resulting in accumulation of Ca and Mg in the rhizosphere (Lorenz et al., 1994; Roose and Kirk, 2009). As a consequence of the low concentrations in the soil solution, mass flow fulfills only a minor part of plant's requirement for K, P, and micronutrients. Barber (1995) estimated for maize that mass flow contributed only 18% of K uptake and as little as 5% of P uptake.

When nutrient flux by mass flow is smaller than nutrient uptake, the nutrient concentration in the rhizosphere will decrease. Such depletion is expected to take place for those nutrients that occur at low concentration in the soil solution and/or for which the plant demand is large (Roose and Kirk, 2009). The resulting depletion zones around growing, single roots were first evidenced with autoradiographs of maize roots growing in radiolabeled soils by Lewis and Quirk (1967). The concentration gradient in the rhizosphere is the driving force for diffusion, which is the major transfer mechanism for poorly mobile nutrients at the soil-root interface. The diffusive flux of nutrients will vary considerably with the effective diffusion coefficient in soils, which is much smaller than the diffusion coefficient in water, because of the many physical and chemical interactions that ions encounter within the soil's solid phase (Tinker and Nye, 2000). This effective diffusion coefficient also depends on the soil water content, tortuosity, and buffering capacity, that is, the ability of the soil solid phase to replenish the soil solution. Although the diffusion coefficient in water is fairly similar among major nutrient ions such as NO₃-, K+, and $H_2PO_4^-$ (1.9 × 10⁻⁹, 2.0 × 10⁻⁹, and 0.9 × 10⁻⁹ m² s⁻¹, respectively), their effective diffusion coefficient in soils spans several orders of magnitude, ranging from 10⁻¹⁰-10⁻¹¹ m² s⁻¹ for NO₃ ions, 10^{-11} – 10^{-12} m² s⁻¹ for K⁺ ions to only 10^{-12} – 10^{-15} m² s⁻¹ for the least mobile H₂PO₄⁻ ions. Such differences are mostly due to differences in the buffering capacity of soils. While H₂PO₄ ions strongly react with soil solid phase, via a whole range of precipitation/dissolution and adsorption/desorption reactions (see below), NO₃ ions are much less prone to such interactions. The buffering capacity of soils for H₂PO₄⁻ ions is thus much larger than that for NO₃ ions, and hence their effective diffusion coefficient is up to 5 orders of magnitude smaller. Consequently, the radial distance from which a nutrient can diffuse toward the root surface, that is, the nutrient depletion zone, varies considerably among nutrients and soils, from centimeters for NO₃ ions, millimeters for K⁺ ions (Figure 6.6), to a fraction of a millimeter for H₂PO₄⁻ ions. This is in agreement with a number of studies that have provided direct estimates of the extent of K and P depletion zones (e.g., Hendriks et al., 1981; Kuchenbuch and Jungk, 1982; Jungk and Claassen, 1986; Darrah, 1993; Begg et al., 1994; Hinsinger and Gilkes, 1996; Hinsinger, 1998; Jungk, 2002).

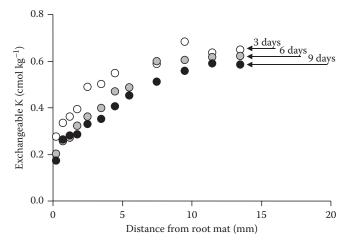

FIGURE 6.6 Depletion of exchangeable K in the rhizosphere of Italian ryegrass (*Lolium multiflorum* cv. Turilo) after 3, 6, and 9 days of growth in a root mat technique in a K-fertilized treatment of the long-term K fertilizer trial in Gembloux, Belgium. (From Hinsinger, P. 1990. Actions des racines sur la libération du potassium et l'altération de minéraux silicatés—Incidences agronomiques. PhD thesis. ENSA Montpellier, France.)

Ge et al. (2000) calculated the extent of the total volume of the rhizosphere based on the extent of the depletion zones and root architecture in young common bean plants. Based on their findings, Hinsinger et al. (2005) estimated that for effective diffusion coefficients ranging from 10⁻¹¹ to 10⁻¹³ m² s⁻¹, the volume of the P depletion zones of the whole root system of a young common bean plant is only about 0.4%-3% of the densely rooted topsoil. Such calculations will however underestimate the actual volume of soil supplying H₂PO₄⁻ ions to plants. Indeed, using root-hairless mutants of Arabidopsis thaliana and barley, Bates and Lynch (2001) and Gahoonia et al. (2001) reported that root hairs play a major role in further extending the depletion zone around roots. Based on the SimRoot model, Ma et al. (2001) showed that the density and length of root hairs played a key role in determining P depletion around growing roots. Besides root hairs, arbuscular mycorrhizal (AM) fungi should also be taken into account as their hyphae may provide access to phosphate beyond the rhizosphere depletion zone as stressed by Zhu et al. (2001). Schnepf and Roose (2006) found that the depletion zone around a single hypha was negligibly small when hyphal uptake is small compared with diffusion in soil. More recently, Schnepf et al. (2008) calculated the contribution of AM hyphae to the extent of the P depletion zone. They showed that, provided that hyphae were able to take up P along their entire length, mycorrhizal hyphae can considerably extend the P depletion zone beyond the rhizosphere, which is in agreement with results of Schweiger and Jakobsen (1999). Li et al. (1991) showed that the extent of the depletion zone of P by AM plants is up to several centimeters from the root surface, compared with several millimeters in nonmycorrhizal plants. Schnepf et al. (2008) thus concluded that most P uptake of mycorrhizal plants occurs via the hyphae, which also means that much of the transport of

poorly mobile nutrients such as P occurs via the hyphal network. However, this conclusion is based on a model at the scale of a single root and will need to be upscaled to the whole root system for drawing definitive, more ecologically relevant conclusions. Dunbabin et al. (2006) have shown the extra benefit of a whole root system model compared with a single root model for predicting P acquisition in the rhizosphere. Accounting for rapid root growth, as can be done only in a whole root system model, may provide a better indication of the relative contribution of roots and mycorrhizal hyphae to P transport and uptake in the (mycor)rhizosphere.

In contrast with the abundant literature on gradients of major nutrients in the rhizosphere, the transport of micronutrients is much less well documented. Lorenz et al. (1994) estimated that diffusion was a major transport pathway for Zn in the rhizosphere of radish and the depletion profiles of various pools of soil Zn were shown by Kirk and Bajita (1995) in the rhizosphere of lowland rice. Recently, Bravin et al. (2009b) showed that the gradient of Cu concentration (both for soil solution total Cu and Cu²⁺) in the rhizosphere of durum wheat extended over several millimeters, that is, much beyond the depletion zone expected to occur for a poorly mobile micronutrient such as Cu. However, Bravin et al. (2009b) suggested that the observed decrease in soil solution Cu was the consequence of root-induced increase in rhizosphere pH rather than Cu uptake and diffusion. Hence, mechanisms other than biophysical processes must be taken into account to fully understand nutrient patterns in the rhizosphere.

6.4 Rhizosphere Biogeochemistry

6.4.1 Gas Exchange and Redox Processes

Gas exchange occurs in the rhizosphere primarily as a consequence of respiration of roots and the surrounding microorganisms, which results in a decrease in pO₂ and increase in pCO₂. The decline in pO₂ leads to a decrease in soil redox potential, thereby affecting many biogeochemical cycles. Most plant species are sensitive to hypoxia/anoxia, whereas wetland plant species have evolved specific strategies to cope with hypoxic conditions. The adaptation of wetland plants to hypoxic (submerged) soils is based on the development of a special tissue within their roots, the so-called aerenchyma, which conducts O₂ from the shoots (Armstrong, 1979). Leakage of part of this O2 can result in an increase in pO2 in the rhizosphere of wetland plants species (Flessa and Fischer, 1992; Revsbech et al., 1999; Armstrong et al., 2000). Most of the reported direct measurements of redox potential in the rhizosphere of rice plants were conducted only at the surface of the roots (Flessa and Fischer, 1992; Revsbech et al., 1999; Bravin et al., 2008). However, Begg et al. (1994) reported oxidation of Fe2+, which is dominant in the soil solution under reduced conditions of submerged soils, extending several millimeters from the surface of rice roots. In the rhizosphere of wetland plant species, the well-documented formation of the so-called iron plaque is due to (1) the oxidation of Fe2+ to Fe3+ (Begg et al., 1994; Kirk and Bajita, 1995) and (2) the subsequent precipitation of ferric iron oxides (e.g., goethite), due to the low solubility of these Fe³+ minerals (Bacha and Hossner, 1977). These studies and that of Bravin et al. (2008) have shown that iron plaque occurs in the root apoplasm and on the surface of the roots. Besides O_2 leakage from root aerenchyma, Trolldenier (1988) reported that part of the oxidation in the rhizosphere of lowland rice was due to Fe²+-oxidizing bacteria. Neubauer et al. (2007) showed for *Juncus effusus L*. that rhizosphere oxidation was partly mediated by lithotrophic bacteria. In addition to the formation of iron plaque in wetland plant species, Mn²+ can also be oxidized leading to formation of manganese oxides at the surface of roots growing in reduced soil conditions (e.g., Bacha and Hossner, 1977).

In contrast to the wealth of studies in reduced soil conditions, there have been only few published reports of decreased pO₂/redox potential in the rhizosphere of plants growing in oxic conditions. Using arrays of redox microelectrodes, Fischer et al. (1989) found that redox potential decreased from 700 to less than 380 mV in the vicinity of a growing root tip of faba bean. One day later, after the root apex had passed the microelectrode due to root growth, redox potential increased to its initial value of 700 mV. This can be explained by the high respiration rate in the meristematic zone of the root, as shown by Bidel et al. (2000) in roots of peach tree seedlings. The meristematic region of the root is known for its intense metabolic activity and respiration, particularly in growing roots. Bidel et al. (2000) reported that O2 consumption increased sevenfold in an actively growing root apex compared with that in nongrowing roots, reaching values greater than 35×10^{-14} mol O₂ s⁻¹. These authors also estimated the flux of O₂ due to microbial respiration in the rhizosphere of roots growing in agar gel, which decreased abruptly from 10 to 1 nmol O₂ m⁻³ gel s⁻¹ at 300 μm from the root surface near the apex. Cornu et al. (2007) monitored the redox potential in the rhizosphere of tomato with daily resolution, in oxic soil conditions. They showed that the iron status of tomato plants had no significant effect on the redox potential of the rhizosphere, in spite of an increased reductase activity at the root surface as a result of Fe deficiency. Increased reductase activity is part of the strategy of acquisition of Fe of most plant species (all but Poaceae) and is the consequence of the activity of plasmalemma-bound enzymes that are activated under Fe-deficient conditions as frequently occurring in calcareous soils (Marschner, 1995; Robin et al., 2008).

Because of the respiration of belowground organisms and roots, bulk soil pCO $_2$ is commonly 10- to 100-fold larger than atmospheric pCO $_2$ (360 μ mol mol $^{-1}$). Given that roots and microbes are major contributors to soil respiration, the rhizosphere should be a hot spot of elevated pCO $_2$, particularly in the region behind the apex of actively growing roots, in line with the decreased pO $_2$ reported by Bidel et al. (2000). This is, however, little documented in soils. To our knowledge, the only study is that of Gollany et al. (1993), who measured pCO $_2$ values as high as about 100,000 μ mol mol $^{-1}$ at 1–3 mm from the root surface. As stressed by Hinsinger et al. (2009), it is rather astonishing that in contrast with the current attention on aboveground pCO $_2$, so little data is available about rhizosphere pCO $_2$ and its impact on belowground organisms and biogeochemical cycles.

6.4.2 Acidification and Alkalization

In addition to the above-mentioned processes, the respiration of roots and microorganisms can also significantly alter the rhizosphere pH. Respired CO_2 rapidly forms the weak acid $\mathrm{H}_2\mathrm{CO}_3$ (pK=6.36) in water. Thus, except for the most acidic soils, where $\mathrm{H}_2\mathrm{CO}_3$ remains undissociated, the increase in p CO_2 will result in rhizosphere acidification. Based on the values of p CO_2 in the rhizosphere measured by Gollany et al. (1993) and on the relationship between pH and p CO_2 in calcareous soils based on the calcite dissolution/precipitation equilibrium, Hinsinger et al. (2003) calculated that in situ rhizosphere pH values could be as low as about 6.7–6.8, compared with 8.3 at atmospheric p CO_2 . However, such a change in rhizosphere pH by root and microbial respiration is surprisingly little documented and normally not taken into account in studies of rhizosphere biogeochemistry.

In contrast, the control of rhizosphere pH by proton influx/ efflux from roots has been extensively studied, as reviewed by Nye (1981) and Hinsinger et al. (2003). When the influx of cations into root cells is greater than that of anions, the excess of positive charges entering the roots is counterbalanced by a net efflux of protons and thus rhizosphere acidification (Hinsinger et al., 2003), whereas alkalization occurs if there is a net influx of excess anions over cations. All charged ionic species that are released from roots, such as carboxylates, which can be exuded in large amounts by roots of some plant species (Jones, 1998; Hinsinger et al., 2003), need to be taken into account in this balance. Among inorganic ions, nitrogen has a major impact on root-mediated pH changes in the rhizosphere because it is taken up in large amounts as either an anion (nitrate) or a cation (ammonium) or even as the uncharged species N2 in plant species such as legumes, which rely on symbiosis with N2-fixing bacteria. The uptake of nitrate will result in rhizosphere alkalization, while the uptake of ammonium and, to a lesser extent, N, fixation result in rhizosphere acidification (Riley and Barber, 1971; Marschner and Römheld, 1983; Gahoonia et al., 1992; Plassard et al., 1999; Tang et al., 2004). Rhizosphere alkalization confers an adaptative advantage on plants growing in acid soils, as it can alleviate toxicities of aluminum (Pineros et al., 2005) and other metal cations such as copper (Michaud et al., 2007; Bravin et al., 2009a, 2009b). Increased proton efflux from roots, and thus rhizosphere acidification, is well known as an adaptive response of many plant species to both Fe and P deficiencies (Römheld and Marschner, 1989; Hinsinger, 2001; Tang et al., 2004; Robin et al., 2008). Riley and Barber (1971), and many others, have shown that rhizosphere pH changes can dramatically alter the acquisition of P. In most soils, rhizosphere acidification as a result of ammonium supply leads to improved P acquisition by plants, relative to plants fed with nitrate (Riley and Barber, 1971; Gahoonia et al., 1992; Hinsinger and Gilkes, 1996; Hinsinger, 2001). However, as pointed out by Gahoonia et al. (1992) and Hinsinger (2001), rhizosphere alkalization may enhance P acquisition in other soils, for example, acidic oxisols. Using a mechanistic modeling approach, Devau et al. (2009, 2010) suggested that rhizosphere alkalization could also result in a redistribution of P sorbed onto the various positively charged minerals in a neutral soil. In an acidic soil, Pearse et al. (2006a, 2006b) showed that wheat and oilseed rape were more P efficient than white lupin, due to their ability to increase the rhizosphere pH and in spite of their reduced capacity to exude large amounts of carboxylates compared with white lupin cluster roots. Recently, Bravin et al. (2009a) reported in a Cu-contaminated, acidic soil (bulk soil pH = 4.6-4.8) a considerable increase in rhizosphere pH (pH = 7.5) for nitrate-fed durum wheat, compared with ammonium-fed plants (pH = 3.9). As a consequence of the strong alkalization in the rhizosphere of nitrate-fed durum wheat, the soil solution Cu concentration in the rhizosphere and thus Cu uptake by plants were considerably lower than those in ammonium-fed durum wheat. Their study also showed that rhizosphere pH can be more than 2pH units above bulk soil pH. A number of studies have reported that rhizosphere acidification, which occurs as a consequence of N₂ fixation in legumes or ammonium supply in other plant species, can lead to a pH decrease of up to about 2 pH units compared with the bulk soil (e.g., Gahoonia et al., 1992; Li et al., 2008). Soil pH has a dramatic effect on below-ground organisms as stressed by recent biogeographical studies at various scales, from global to field scale, for example, Fierer and Jackson (2006) and Philippot et al. (2009a). Hence, root-induced pH changes may be a major driver of microbial communities and their function in the rhizosphere.

Beside roots, rhizosphere microorganisms can also produce carboxylates and protons (carboxylic acids), thereby contributing to rhizosphere acidification. This has been well documented for ectomycorrhizal and saprophytic/pathogenic fungi, among which some species have been shown to release massive amounts of oxalic acid (Dutton and Evans, 1996; Wallander, 2000; Casarin et al., 2004). In lowland rice, the coupling of rhizosphere pH changes with redox processes has also been documented for ferrous iron oxidation and the subsequent ferric iron oxide precipitation (e.g., Begg et al., 1994). Begg et al. (1994) calculated that this process accounted for a major proportion of rhizosphere acidification, aside from the uptake of ammonium, which is the major form of nitrogen under reduced conditions.

6.4.3 Inorganic Nutrient Mobilization

6.4.3.1 Desorption and Ligand Exchange

Many nutrient anions (e.g., SO₄²⁻, HPO₄²⁻) are adsorbed on positively charged soil constituents with large specific surface areas, mostly metal oxides and clay minerals (Okazaki et al., 1989; Kudeyarova, 1991; Saeki and Matsumoto, 1998; Gustafsson, 2001). This surface sorption reduces anion diffusion to the root; consequently, plants have found ways to accelerate desorption of nutrients held on these surfaces. In most soils, these exchange surfaces are composed of Fe and Al (hydr)oxide minerals (e.g., gibbsite, hematite, ferrihydrite, goethite) as well as clay minerals (e.g., kaolinite, illite, smectite) as recently stressed by the work of Devau et al. (2009, 2010). These minerals present –OH and –OH₂ groups on their surfaces. One or two of the OH⁻ groups on anions such as H₂PO₄⁻ can substitute an –OH group on the mineral surface, thereby forming a monodentate or bidentate

ligand inner sphere complex. Although pH dependent, ligand exchange takes place even if the net surface charge is the same as that of the adsorbate. These anions are not held irreversibly; however, a higher concentration of other anions in the soil solution may subsequently displace them through ligand exchange. In a rhizosphere context, most interest has focused on the role of organic acid anions (e.g., citrate³⁻, oxalate²⁻) in ligand exchange and P release from mineral surfaces (Jungk et al., 1993; De Cristofaro et al., 2000; Hinsinger, 2001; Essington and Anderson, 2008). Although it is quantitatively difficult to separate between mineral dissolution, ligand exchange, and other indirect processes that can occur when organic acids are introduced into soil (e.g., changes in pH and ionic strength), it is clear that ligand exchange plays a role in nutrient mobilization in the rhizosphere. It appears that ligand exchange is greater for di- and tricarboxylic acids than that for monocarboxylic acids and that high concentrations of competing anions are required for the process to be of significance (Jones, 1998). More work is required to quantify the significance of ligand exchange compared with other nutrient mobilization mechanisms. For this purpose, the use of mechanistic modeling will provide new opportunities, as recently exemplified in the work of Devau et al. (2010) who showed that, in addition to P uptake, root-induced alkalization and Ca uptake had to be accounted for in order to properly simulate the observed changes of P availability in the rhizosphere of durum wheat, as a result of complex interactions with surface charges and P adsorption on the various P-sorbing soil minerals.

6.4.3.2 Complexation and Chelation

Complexes and chelates play an important role in nutrient acquisition and therefore in microbe-microbe and plantmicrobe interactions. Complexation by microbial and plant carboxylates and phenolic compounds increases the availability of P and trace elements (e.g., Gerke, 1993; Hu et al., 2005). Carboxylates increase P availability by two mechanisms: anion (ligand) exchange and solubilization of Fe and Al (Gerke and Hermann, 1992). Due to the neutral cytoplasmic pH, carboxylates are released as anions (deprotonated); therefore, they do not decrease per se the soil pH (Jones, 1998; Hinsinger et al., 2003). As mentioned above, the carboxylate anions compete with phosphate anions for binding sites, thus releasing P into the soil solution (Gerke, 1993, 1994). A large proportion of P in soils is bound to humic-Fe-complexes and to amorphous Fe-oxides (Gerke and Hermann, 1992). Carboxylates form water-soluble complexes with Fe and Al, thereby decreasing the free Fe and Al ion concentration in the rhizosphere soil solution. This leads to increased solubilization of Fe3+ or Al3+ and thus release of P bound to Al/Fe oxides or bound to clays and organic matter via Fe/Al bridges (Gerke et al., 2000).

Chelates are small organic molecules that bind metals and change their charge. This changes the behavior of metals in the soil, particularly if the chelate-metal complex has a negative charge because it will be repulsed from negatively charged surfaces, for example, clays and organic matter. Moreover, chelation leads to increased release of metals from soil particles (e.g., metal

oxides) to regain the equilibrium concentration of ionic forms in the soil solution.

Chelates that bind Fe have been extensively studied because of their important role in Fe uptake by plants and microbes. Plants can be divided in two groups based on their Fe acquisition mechanism: Strategy I and Strategy II plants (Marschner, 1995). Dicots and nongraminaceous plants employ Strategy I: under Fe deficiency, they increase the Fe reductase activity of the roots, release protons to decrease the rhizosphere pH, and may also increase the exudation of chelating compounds such as phenolics. Graminaceous plants (Poaceae, Strategy II) respond to Fe deficiency by releasing phytosiderophores (nonproteinogenic amino acids such as mugineic acid) (Takagi, 1976; Marschner, 1995; Robin et al., 2008), which preferentially chelate Fe but can also bind Zn, Mn, or Cu. The Fe-PS complexes are taken up intact by root cells, Fe reduction taking place in the cells (Römheld, 1991; Marschner, 1995). Cereal species differ in capacity to release phytosiderophores under Fe deficiency, with barley and wheat releasing more than maize and sorghum (Römheld and Marschner, 1989; Marschner, 1995). Phytosiderophores are also released in response to Zn deficiency (Zhang et al., 1991). However, it is not clear if this is a separate regulation of phytosiderophore release or due to impaired Fe metabolism induced by Zn deficiency.

Microorganisms also release chelating compounds under Fe deficiency: organic acids, but more importantly, siderophores, which can be classified as hydroxamates or catechols (Neilands, 1984; Hoefte, 1993; Robin et al., 2008). A given microbial species may produce one or several siderophores (Bossier et al., 1988; Raaijmakers et al., 1995). The utilization of different siderophores, particularly those released by other microorganisms, appears to be important for the competitive ability of bacteria (Mirleau et al., 2000; Lemanceau et al., 2009). Bacterial siderophores are a poor iron source for plants (Bar-Ness et al., 1991) and can inhibit Fe uptake by plants (Becker et al., 1985). On the other hand, certain fungal siderophores such as rhizoferrin have been shown to increase Fe uptake by plants (Yehuda et al., 1996). The affinity of a given chelator for iron can be expressed as stability constant; the higher the stability constant, the greater the affinity of the chelator to Fe (Table 6.2). Bacterial siderophores such as ferrioxamine have a greater affinity to Fe than phytosiderophore (Table 6.2) (Crowley et al., 1991). Thus, if present at similar concentrations, Fe will bind preferentially to siderophores rather than phytosiderophores. Fe uptake by roots and

TABLE 6.2 Apparent Stability Constants Fe

Chelating Compound	Apparent Stability Constant
Mugineic acid (phytosiderophore)	19.1

Source: Taken from Yehuda, Z., M. Shenker, Y. Hadar, and Y. Chen. 2000. Remedy of chlorosis induced by iron deficiency in plants with the fungal siderophore rhizoferrin. J. Plant Nutr. 23:1991–2006. With permission from Taylor & Francis.

translocation into shoots of maize is significantly lower if Fe is supplied bound to siderophores compared with Fe-PS (Crowley et al., 1992). On the other hand, phytosiderophores are good Fe sources for microbes (Jurkevitch et al., 1993).

6.4.3.3 Dissolution and Precipitation of Minerals

Soil nutrients occur in a number of minerals that can release their constituents via dissolution processes. Alternatively, nutrients can be immobilized by precipitation processes. These dissolution/ precipitation processes can be promoted in the rhizosphere as a consequence of changes in pH and concentrations of cations or anions, including organic ligands. The mobilization of nutrients in the rhizosphere is well documented for K and P (for P, see above). Hinsinger et al. (2001) reported that roots can also increase the dissolution rate of a number of other nutrients (Ca, Mg, Si) when supplied as a basalt rock powder, with the strongest dissolution rate for Fe. Hinsinger and Jaillard (1993) demonstrated in ryegrass that K uptake by roots and the resulting decrease in solution K concentration is the driving force for the selective dissolution of a phlogopite mica, with the rate of release of interlayer K from phlogopite and biotite micas increasing approximately five- to sixfold, compared with unplanted control (Hinsinger et al., 2006). This rhizosphere depletion of K in the soil solution also explains the results of long-term fertilizer trials conducted in Europe showing that the release of nonexchangeable K can amount up to 100 kg K ha-1 year-1 over several decades (Hinsinger, 2002). The magnitude of the release of nonexchangeable K was expected to be negligible in such temperate, arable soils, because their bulk soil solution K concentration typically ranges from 100 to 1000 μM. Indeed, Springob and Richter (1998) showed that the rate of release of nonexchangeable K is almost nil at such soil solution concentrations. They also showed that the release of nonexchangeable K is strongly enhanced at soil solution K concentrations below 3 µM, which is the range of concentration expected to occur close to maize roots, according to the estimations by Claassen and Jungk (1982). Thus, the depletion of soil solution K in the rhizosphere is the driving force of the release of interlayer K and concomitant dissolution of micaceous minerals in soils (Hinsinger and Jaillard, 1993; Hinsinger et al., 2006). Barré et al. (2007) showed that the uptake of K by ryegrass quantitatively matches the increased amount of interstratified illitesmectite minerals in the rhizosphere, forming at the expense of the illite-like clay minerals. Their findings are in agreement with those of Kodama et al. (1994) who reported earlier an increased amount of interstratified illite-vermiculite minerals in the rhizosphere of field-grown maize plants compared with the bulk soil. Accumulation of easily available K in the rhizosphere has also been found in situ for field-grown plants such as forest trees (e.g., Turpault et al., 2005). This is probably due to the combination of uptake-driven depletion and weathering of K-bearing minerals, which, over longer timescales, may contribute a net increase in soil solution and exchangeable K in the rhizosphere.

Changes in rhizosphere pH are also major determinants of dissolution/precipitation equilibria of nutrient-bearing minerals as shown for, for example, Mg (Hinsinger et al., 1993;

Calvaruso et al., 2006) and P (Gahoonia et al., 1992; Begg et al., 1994; Hinsinger and Gilkes, 1996; Bertrand et al., 1999). Rhizosphere acidification induced by oilseed rape induces the formation of hydroxy-interlayered vermiculite and concomitant release of metal cations such as Mg (Hinsinger et al., 1993). The role of rhizosphere pH in the biologically mediated dissolution of silicate minerals has been studied in detail in forest tree seedlings (Wallander and Wickman, 1999; Bakker et al., 2004). Ectomycorrhizal fungi were largely responsible for elevated concentrations of citric and oxalic acids, resulting in mobilization of K and Mg from biotite (Wallander and Wickman, 1999). This mobilization may be due to a direct pH effect or the complexation by carboxylates, which also affects the dissolution of silicate minerals (Huang and Keller, 1970; Jones et al., 1996; Jones, 1998). The direct impact of pH changes on the weathering of silicates such as micas and feldspars in the soil around ectomycorrhizal fungal hyphae was shown by Arocena et al. (1999) and Arocena and Glowa (2000). Ectomycorrhizal fungi supposedly play a major role in these processes, rather than the root, as reviewed by Landeweert et al. (2001) and Hoffland et al. (2004). Fungal hyphae are indeed able to dissolve silicate minerals, forming tunnel-like pores inside mineral grains (Jongmans et al., 1997). Moreover, ectomycorrhizal fungi were shown to select for different bacterial communities that produce acidic or chelating metabolites, which also affect the weathering of minerals (Calvaruso et al., 2007; Uroz et al., 2007). Besides silicate minerals, numerous studies with rock phosphate have further proved that H+ release by plant roots can considerably increase the dissolution of apatite-like calcium phosphate minerals and hence the availability of P in the rhizosphere (see Hinsinger, 1998, and many references therein). Some species such as buckwheat, oilseed rape, and legumes have been reported to be particularly efficient in using P from calcium phosphates, which is related to their ability to release H+ (e.g., Aguilar and van Diest, 1981; Amann and Amberger, 1989; Hinsinger and Gilkes, 1995; Zoysa et al., 1998) and/or carboxylic acids (e.g., Hoffland et al., 1989; Ae et al., 1990). The role of P-solubilizing microorganisms (fungi and bacteria) and ectomycorrhizal fungi in enhancing the rates of dissolution of apatite-like calcium phosphate minerals in the (mycor)rhizosphere has been extensively studied (e.g., Wallander, 2000; Reyes et al., 2002).

6.5 Rhizosphere Ecology

6.5.1 Communication, Signaling, and Sensing

In this review, communication is defined as a two-way process between two organisms. For example, one organism releases compounds that are sensed by the other organism, which responds by changing its physiology or by producing other compounds that induce changes in the first organisms' physiology/morphology. Hence, communication requires signaling, sensing, and response. Signaling is the first part of communication. It is a one-way process, that is, a specific compound released by one organism will induce a response in the other. Sensing is a

prerequisite for the response. The signal has to be recognized and understood, which then induces a specific or unspecific response in the sensing organism.

6.5.1.1 Communication between Plants and Microbes

The classical example of communication between plants and microorganisms is the complex exchange of signals between legumes and Rhizobium or plants and pathogens. In legume-Rhizobium interactions, legume roots release flavonoids, which trigger the production of factors that induce nodule formation in the roots, for example, nod factor by Rhizobium. In plantpathogen signaling, certain root exudate components attract species-specific pathogens. A thorough discussion of these classical examples would be beyond the scope of this chapter; the reader is referred to reviews for Rhizobium (e.g., Werner et al., 1994; Lugtenberg et al., 1995) and for plant-pathogen signaling (e.g., Bent, 1996; Hahn, 1996; Knogge, 1996; Walton, 1996; Avis et al., 2008). Various facets of communication in the rhizosphere have also been recently reviewed and critically discussed by Bais et al. (2004), Faure et al. (2009), Hartmann et al. (2009), and Sanon et al. (2009).

Another plant-microorganism communication that has attracted considerable interest is the interaction between plants and plant growth-promoting rhizobacteria/fungi (PGPRs). PGPRs, for example, Azospirillum sp., enhance plant growth directly via phytohormone production (cytokinins, gibberellins, auxin) and improved nutrient uptake (N2 fixation, nitrate reduction, P solubilization) or indirectly by inhibiting pathogens or deleterious bacteria (Lugtenberg et al., 1991; Somers et al., 2004; Raaijmakers et al., 2009; Richardson et al., 2009). More recently, they have been shown to alter gene expression in plants (Wang et al., 2005). The relative importance of these factors for plant growth depends on the plant-microbe combination as well as on environmental conditions. Of general importance is the release of phytohormones by PGPRs (Leinhos and Vacek, 1994), which enhance density and length of root hairs and thus root surface area and can stimulate lateral root growth (Martin et al., 1989; Srinivasan et al., 1997; Ryu et al., 2005; Richardson et al., 2009).

Microorganisms can induce changes in quantity and quality of root exudates (Barber and Martin, 1976; Klein et al., 1988). Moreover, microorganisms may induce plants to produce and release compounds that they can use most efficiently, thus giving them a competitive advantage (Somers et al., 2004). Certain root exudates induce expression of a number of genes in microorganisms, for example, nod gene expression induced by flavonoids as mentioned above, and also antibiotic production by some biocontrol bacteria (Somers et al., 2004; Raaijmakers et al., 2009). Root exudates of non-host plants can induce germination of AM spores (Vierheilig and Ocampo, 1990). On the other hand, glucosinolates or other compounds released by roots can inhibit AM colonization (Vierheilig et al., 2000, 2003).

The role of exudates in plant-microbe communication has been studied extensively. However, roots and microbes can also communicate via other mechanisms. For example, root border cells, or sloughed root cap cells, (living plant cells programmed to separate from the periphery of roots into the external environment) are a uniquely differentiated root tissue that is important for plant–microbe interactions (Hawes, 1991). Root border cells have been shown to be crucial for infection by certain pathogens (Hawes et al., 1997; Zhu et al., 1997).

The outer surface of microorganisms consists of exo- and lipopolysaccharides, which are also important for plant-microbe interactions (Dekkers et al., 1998; Somers et al., 2004). These polysaccharides appear to have signaling function, triggering plant development or modulating defense reactions, and they are important for the colonization of roots as well as for biofilm formation where they create a favorable microenvironment (Dow et al., 2000). Interestingly, root exudates can affect the composition of the polysaccharides and thereby their function (Karpati et al., 1999).

For effective interaction between microorganisms and plants, microorganisms have to be able to colonize and persist in the rhizosphere, particularly when foreign microorganisms are introduced to enhance plant growth. Traits that are important for rhizosphere colonization include motility, high growth rate, ability to synthesize amino acids and vitamin B1, ability to utilize organic acids and certain cell surface proteins, and rapid adjustment to changing conditions (Simons et al., 1997; Lugtenberg and Dekkers, 1999; Hartmann et al., 2009).

6.5.1.2 Communication among Microorganisms

The best known compounds involved in communication between microorganisms are autoinducers such as N-acyl homoserine lactones (AHL) produced by Gram-negative bacteria, cyclic dipeptides produced by pseudomonads, butyrolactone-containing autoinducers produced by *Streptomycetes* sp., and oligo peptides in Gram-positive bacteria (Fray, 2002; Hense et al., 2007; Faure et al., 2009). They are called autoinducers because the producer cells respond to their own signals. Bacterial cells produce and secrete these small signaling molecules, which then move away from the cell by diffusion or mass flow.

Of the autoinducers, AHLs have been particularly well studied for their role in quorum sensing (Faure et al., 2009). A number of different AHLs that differ in side chain chemistry are known (Fray, 2002; Hense et al., 2007); different bacterial species may produce the same AHL with each cell producing and releasing a basal level of AHLs. The purpose of quorum sensing is twofold, taking a census (assessing if the minimum density for effective action has been reached) and coordinating or synchronizing behavior among bacteria in a population or among populations (Winans, 2004).

As the cell density increases, AHLs accumulate in the growth medium. Upon reaching a critical threshold concentration, the AHL molecule binds to its receptor, which activates or represses the expression of certain genes (Somers et al., 2004; Hense et al., 2007). Gantner et al. (2006) used a reporter gene approach to evaluate the maximum distance bacteria could communicate to each other in the rhizosphere via AHLs. They found that the "calling distance" could reach up to about $20\,\mu m$.

AHLs were initially investigated for their role in densitydependent microbial responses, which occur only if a certain cell density is reached, for example, bioluminescence of Vibrio fischeri. They are now known to form a communication network between distinct bacterial populations, for example, inducing of specific genes, gene transfer, or antibiotic production. Other microorganisms may decompose AHLs and thereby intervene in communication (Somers et al., 2004). AHLs also play a role in communication between microbes and plants. They are involved in pathogen attack or infection (or production of cell wall degrading enzymes), which usually occurs only after a critical cell density is reached to ensure that infection is successful. Infection at low density may induce strong and successful defense reactions by the plant, which would reduce infection success and therefore the survival of the pathogen (Fray, 2002). On the other hand, some plants produce compounds that block AHL sensing in bacteria or degrade AHLs, thus preventing the density-dependent response (Hartmann et al., 2009). Moreover, some plants produce AHLs that may induce infection when cell density of pathogen is still too low for successful infection (Fray, 2002).

Quorum sensing as described above assumes that bacteria cooperate and coordinate their activities; that is, that autoinducers have evolved to benefit the population. However, the autoinducer concentration that could function as an estimate of cell density is altered by many factors, including diffusion and mass flow, spatial distribution of the cells, degradation, and the production of the same autoinducer by third parties, whether intentionally or by chance (Hense et al., 2007). This is particularly relevant in the rhizosphere where microbial populations are nonuniformly distributed both in space and time and where, due to the high biodiversity, the same autoinducer may be produced by different microbial species, which could result in chemical manipulation or interference. Moreover, the spatial distribution of cells can have a larger impact on the autoinducer concentration that the cells experience than the density of the cells (Gantner et al., 2006; Hense et al., 2007).

Redfield (2002) proposed that quorum sensing is diffusion sensing, in which the function of secreted autoinducers is to determine whether secreted effectors (e.g., enzymes) would rapidly diffuse away from the cell, thereby allowing bacteria to detect situations in which the disappearance of effectors owing to diffusion is low enough for effector secretion to be efficient. This would mean that autoinducers benefit the individual cell, not the population. Hense et al. (2007) hypothesize that autoinducers are produced for efficiency sensing; that is, the ecologically relevant function of autoinducer sensing is to assess the efficiency of producing diffusible extracellular effectors, as their concentration will be influenced by the same factors that influence the concentration of diffusible extracellular autoinducers. The autoinducer can function as a proxy for the more expensive effectors such as exoenzymes. In the rhizosphere, bacteria are often aggregated in microcolonies. These cell clusters usually arise from the growth and cell division of one cell; they are therefore essentially clonal. The more the cells are clustered together, the sooner the threshold for induction is reached. This, together with the usual positive feedback of autoinducer production, maintains communication within the cell clusters. The fewer and larger these clusters are, the more they will exclude interference from other autoinducer-producing or autoinducer-degrading bacteria, plants, and other eukaryotes.

Induced resistance is an example of interactions between microorganisms occurring via the plant. In induced resistance, one microorganism colonizing the roots of a plant makes the plant resistant to the colonization by certain other microorganisms, for example, AM colonization can induce resistance against root pathogens or even leaf-colonizing fungi but can also reduce colonization by another AM fungus (Demeyer and Hofte, 1997; Vierheilig et al., 2003; Khaosaad et al., 2007; Avis et al., 2008). Compounds involved include salicylic acid, siderophores, and lipopolysaccharides (Somers et al., 2004). Induced resistance is often systemic: the whole plant becomes resistant even if inducing organism and pathogen are spatially separated (Vierheilig et al., 2003; Khaosaad et al., 2007). Therefore, antagonism or direct competition for space or nutrients between microorganisms is unlikely to be involved. Instead, induced resistance is due to changes in host physiology, for example, production of defense compounds. However, the mechanisms involved in induced resistance are in many cases still unclear.

6.5.2 Competition and Facilitation

In competition, two organisms interact for a limited resource, with one organism being more successful (competitive) than the other. Limited resources can be nutrients, water, or space. An overview of strategies to improve competitiveness is given in Table 6.3.

Facilitation means that one organism helps another organism in attaining a certain resource or generally improving growth or fitness.

The two types of interactions are not mutually exclusive: an organism may facilitate uptake of a certain nutrient at a particular point in time but also compete for the same or another nutrient at a different time. The balance between competition and facilitation depends on the partners involved as well as environmental conditions.

An example for the continuum between facilitation and competition between plants and microorganisms are mycorrhiza (Johnson et al., 1997). They can cause growth depression in the early stages of plant growth, when the C drain by the fungus outweighs its benefit to the plant in terms of improved P uptake (Buwalda and Goh, 1982; Koide, 1985; Peng et al., 1993; Graham and Abbott, 2000; Li et al., 2005); but in the later stages of plant growth, mycorrhiza can be beneficial by facilitating P and trace element uptake, reducing heavy metal toxicity, etc. Competition may dominate in soils with high P availability where the benefit from mycorrhiza is low or where photosynthesis is reduced, for example, under low light conditions. Facilitation will dominate in soils with low P availability or when the rate of photosynthesis is high; thus, assimilation supplies sufficient C to meet plant and fungal demand. For a comprehensive review of the costs and benefits of mycorrhiza, the reader is referred to Smith and Read (2008).

Compounds that inhibit microbial growth play an important role in competition between microorganisms. Whereas antibiotics are relatively unspecific, bacteriocins are defined as compounds that are produced by several bacterial species and that act specifically on other strains of the same, or closely related, species. Mazzola et al. (1992) showed that production of antibiotics is important for the survival of introduced strains in soil. Microbes may also inhibit the growth of other microbes by competition for iron, HCN release, chitinases, or glucanases that degrade microbial cell walls (Somers et al., 2004).

6.5.2.1 Competition and Facilitation with Respect to Iron

Competition and facilitation with respect to Fe can occur between microorganisms and between microorganisms and plants (Robin et al., 2008). Interactions between microorganisms

include utilization of own and foreign siderophores (the latter is known as cheating), ligand exchange between siderophores, and decomposition of siderophores (Buyer and Sikora, 1991; Loper and Buyer, 1991; Loper and Henkels, 1999). As mentioned in Section 6.4.3.2, the utilization of different siderophores appears to be important for the competitive ability of bacterial strains (Mirleau et al., 2000). Previously, siderophores were thought to be important for biocontrol of pathogenic fungi in some *Pseudomonas* strains; however, it is now clear that in most cases biocontrol is due to antibiotic production (De Weger et al., 1986; Leong, 1986; Loper, 1988; Thomashow and Weller, 1990; Hamdan et al., 1991; Pal et al., 2000; Raaijmakers et al., 2009).

Competition for Fe between plants and microorganisms appears to be strongly in favor of microorganisms (Figure 6.7). Although plants can utilize Fe bound to bacterial siderophores, they are considered to be poor Fe sources for plants (Wang et al., 1993; Walter et al., 1994). On the other hand, phytosiderophores are good Fe sources for microbes (Jurkevitch et al., 1993) and microorganisms decompose phytosiderophores, thereby decreasing Fe uptake by grasses (Von Wiren et al., 1995). Moreover, Fe uptake by roots and translocation into shoots of maize is much lower for Fe siderophores than that for Fe phytosiderophores (Crowley et al., 1992). This raises the question how plants can take up sufficient Fe. For grasses, Crowley and Gries (1994) hypothesized that due to the high release rates of phytosiderophores at the root tip in the first few hours after onset of light (Zhang et al., 1991), the rhizosphere would be flooded with phytosiderophores. The concentration of bacterial siderophores and decomposition rate of phytosiderophores would be relatively low due to the low microbial density at the root tip.

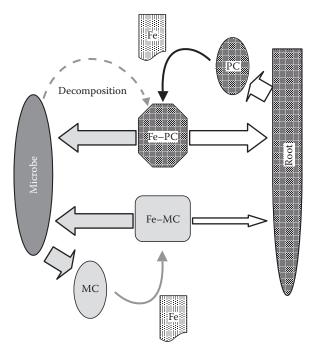

FIGURE 6.7 Interactions between microorganisms and plants for Fe. MC, microbial chelator; PC, plant chelator; Fe–MC, Fe–PC, iron chelated by microbial or plant chelator.

Thus, the concentration of phytosiderophores would be far greater than that of bacterial siderophores, outweighing the higher affinity of Fe for siderophores (Robin et al., 2008). This is in agreement with the model developed by Darrah (1991), which demonstrates that spatially and temporally constrained production of an exudate makes it more efficient. In addition, facilitation occurring between two plant species has been reported in intercropped Strategy I and Strategy II plant species, resulting in improved iron uptake in the legume plants close to rows of the cereal crop (Zuo et al., 2000; Gunes et al., 2007). This suggests that Fe uptake by Strategy I plant species was improved as a consequence of phytosiderophore release by the neighboring Strategy II plant species.

6.5.2.2 Competition and Facilitation with Respect to Phosphorus

Plants and microorganisms in the rhizosphere may also compete for P. Plants and microorganisms have evolved similar mechanisms to increase P availability, such as release of carboxylates or phosphatases or changes in pH (Dinkelaker and Marschner, 1992; Gahoonia and Nielsen, 1992; Jones, 1998; Whitelaw et al., 1999; Hinsinger, 2001; Hinsinger et al., 2009; Richardson et al., 2009). Additionally, plants and fungi can increase the soil volume exploited by growing roots, root hairs, or hyphae (Foehse et al., 1988; Hinsinger et al., 2005). Plants and microorganisms compete for the mobilized P. Additionally, microorganisms can decompose carboxylates released by plant roots (Ström et al., 2001), thereby decreasing the effectiveness of the carboxylates. Microorganisms are highly competitive for P compared with plants, particularly when plant residues are the P source (McLaughlin et al., 1988). McLaughlin et al. (1988) showed that when P was applied as inorganic fertilizer, less than 5% of the applied P was immobilized in the microbial biomass compared with more than 10% of applied P taken up by the plants. However, when P was added as residue, more than 20% of applied P was found in the microbial biomass compared with less than 10% in the plants.

On the other hand, it has been argued that P immobilized in the microbial biomass may facilitate plant P uptake in the long term due to release of P when part of the microbial biomass dies off (Seeling and Zasoski, 1993; Oberson et al., 2001). Hence, the microbial biomass can be regarded as a labile P pool. Indeed, immobilization and release occur simultaneously: part of the microbial population may immobilize P whereas another part dies off and releases P from the cells. This may explain why microbial biomass P in the rhizosphere can be positively correlated with plant P uptake (Marschner et al., 2006). Since microbial growth in soils is predominantly C limited (De Nobili et al., 2001), C availability governs the balance between immobilization and release of P from the microbial biomass. At low C availability, growth rates and thus P immobilization will be low; previously stored P could be released when part of the microbial biomass dies off. On the other hand, when C availability is high, rapid microbial growth and thus P demand will result in strong net immobilization. Turnover of microbial biomass can be very rapid; within a few days, net P uptake can be replaced by net P release (Figure 6.8). Annual biomass P flux has been estimated to range between 7 and 23 kg P ha⁻¹ year⁻¹ (Brookes et al., 1984). Additionally, microbial P (and N) demand is also affected by growth stage (Tezuka, 1990; Makino et al., 2003). During exponential growth (at high C availability and low cell density), N and P demand is high because they are required for synthesis of DNA, proteins, and cell membranes. As C is depleted, the cells will enter stationary growth; in this phase, N and P demand is low, which can result in net N and P release from microbial biomass.

Moreover, the balance between immobilization and mobilization may also be affected by microbial community structure. A high percentage of strong P mobilizers in a community may result in net mineralization because mobilization exceeds immobilization. On the other hand, a low percentage of strong P mobilizers could lead to net immobilization because mobilization cannot meet P demand. The latter community may utilize P mobilized by plant exudates.

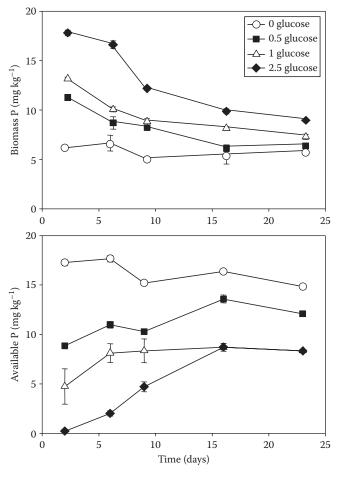

FIGURE 6.8 Available P (resin P) and microbial P in soil after addition of C as glucose at 0, 0.5, 1, and 2.5 g C kg⁻¹ soil. (From Springer Science + Business Media: Marschner, P. 2008. The role of rhizosphere microorganisms in relation to P uptake by plants, p. 165–176. *In* P.J. White and J.P. Hammond (eds.) The ecophysiology of plant-phosphorus interactions. Springer, New York.)

Nutrient facilitation among plants with respect to P has been shown in intercropped legume–cereal species (Li et al., 2007). The legume may facilitate P acquisition by the intercropped cereal either via the release of exudates such as carboxylates (Horst and Waschkies, 1987; Ae et al., 1990; Zhang and Li, 2003; Cu et al., 2005) or phosphatase enzymes (Li et al., 2004; Gunes et al., 2007). Another P-mobilizing mechanism may be protons released by N₂-fixing legume (Hinsinger et al., 2003; Tang et al., 2004, Li et al., 2008). Part of these complex, positive interactions between two plant species may also be due to their ability to access complementary resources, that is, different pools of soil P, which may also be a consequence of differential rhizosphere microbial communities (Li et al., 2008). Hence, besides rhizosphere-based facilitation, niche complementarity may be a major component of the positive interaction observed between intercropped plant species.

Competition and facilitation between plants and microorganisms, among plants, and among microorganisms play a key role in plant-plant and plant-microbe interactions. However, interactions are rarely solely competitive or beneficial; in most cases, there is a continuum between competition and facilitation, which is governed by signal exchange, nutrient supply, and environmental conditions. Although competition for nutrients between two organisms may be heavily in favor of one of the organisms, the other organism may be able to manipulate the competitive ability of the dominant organism or develop other strategies to acquire sufficient nutrients. The discovery of autoinducers has revealed exciting aspects of the interactions not only among microorganisms but also between plants and microorganisms. The use of microarrays now allows studying gene expression in plants and microorganisms, which will lead to further elucidation of the web of interactions that occur in the interface between plants, soil, and microorganisms.

6.6 Conclusions: A Unique, Multifaceted, and Complex Interface

The rhizosphere is a unique soil compartment in which plantand microbial-induced processes are most intense. The properties of the soil and environmental factors such as soil water and aeration modulate the processes occurring in the rhizosphere; however, it is the effect of roots and microorganisms that shape this environment. The rhizosphere properties are a function of the activity of roots and microorganisms; compounds released on the one hand and uptake of nutrients and water on the other. However, roots and rhizosphere microorganisms do not act in isolation; they compete for nutrients and exchange signals that may inhibit or promote growth and metabolism. In many cases where nutrients are mobilized, it is currently not possible to distinguish between the plant and microbial effect. Consequently, we need to develop new ways in which to determine the relative contribution of each and their potential interaction (i.e., synergistic, antagonistic effects). Techniques such as stable isotope probing of microbial function, NanoSIMS, high-throughput DNA sequencing, isotopic-enriched metabolomics, or proteomics may allow us to disentangle the complex interactions between plants and microbes. In particular, the rapid development of "omics" platforms is beginning to transform our understanding of rhizosphere ecology (Mochida and Shinozaki, 2010). As never before, these tools have allowed researchers to produce a massive amount of information through in situ measurements and analysis of natural microbial communities, both vital approaches to the goal of unraveling the interactions of microbes with roots and with one another (Dill et al., 2010). While genomics can provide information regarding the genetic potential of microbes and roots, proteomics characterizes the primary end-stage product, proteins, thus conveying functional information concerning microbial and root activity. Advances in mass spectrometry instrumentation and methodologies, along with bioinformatics approaches, have brought this analytical chemistry technique to relevance in the biological realm due to its powerful applications in proteomics (Keller and Hettich, 2009). However, the application of these new techniques also brings new challenges, particularly, the transformation or data mining of these massive datasets (bioinformatics).

Historically, we have been limited by the poor spatial resolution of rhizosphere sampling techniques that fail to differentiate between root and microbial processes. Some of the newly developed techniques such as NanoSIMS provide a partial solution to this, allowing visualization of nutrient flows at the submicron scale via stable isotopes (e.g., $^{13}\mathrm{C},\,^{15}\mathrm{N},\,^{18}\mathrm{O})$ and microbes (species/function) via molecular tags. However, as the spatial resolution is so high (nm scale) and the sample preparation time so long, it means that obtaining a complete picture of the whole root system remains logistically impossible.

These examples highlight one of the most important challenges in rhizosphere ecology, which is the scaling up from single root regions, to whole root systems, and then to field and ecosystem level (Standing et al., 2007). While single root scale measurements can be useful for some end users (e.g., plant breeding, bioremediation), typically it is only at the bigger scale that most of our results become meaningful to the majority of end users (e.g., in policymakers, environment regulators, agronomists). Mathematical modeling provides complementary approaches for this purpose (e.g., for predicting nutrient dynamics at the field level to allow better targeting of fertilizers; Roose and Kirk, 2009). The improved understanding of the rhizosphere processes will help plant breeders in selecting genotypes with particular ability to mobilize nutrients themselves or create conditions that maximize the mobilization potential of the rhizosphere microbial community.

7.1 Introduction

Soil organic matter (SOM) represents the largest terrestrial carbon (C) pool being almost three times that present in plant and animal biomass. SOM is not a uniform substance, but occurs in a myriad of different molecular forms, whose chemical properties and interactions with the abiotic mineral matrix allow them to be placed in conceptual pools. Knowledge of the size and fluxes of C from these SOM pools is indispensable to predict C turnover in soils as a function of environmental changes. The amount of C stored in a soil is determined by a dynamic equilibrium between C inputs from primary biomass production and C outputs mainly by mineralization, but also from leaching and erosion. Understanding the controls on this equilibrium is an important scientific issue for two reasons:

Feedback: Large quantities of carbon are stored in SOM, and release of this carbon into the atmosphere as CO₂ or methane would have a serious impact on global climate. There are first reports that, as the earth warms, SOM is being oxidized at an increasing rate (Bellamy et al., 2005; Powlson, 2005; Davidson and Janssens, 2006; von Lützow and Kögel-Knabner, 2009). Quantifying these carbon cycle-climate feedbacks is difficult because of the limited understanding of the processes by which carbon and associated nutrients are transformed or recycled

within ecosystems, in particular within soils, and exchanged with the overlying atmosphere (Heimann and Reichstein, 2008). Below-ground processes in particular are still poorly understood, yet provide a number of potentially important feedbacks in the carbon-cycle-climate system (Scheffer et al., 2006; Torn and Harte, 2006). It follows that better predictions of the magnitude of soil carbon feedback reactions require an improved mechanistic understanding of processes that protect SOM against decomposition.

Soil carbon sequestration: A large body of literature suggests that terrestrial sequestration of carbon through land management changes should be considered an option for mitigating climate change. Analyses reviewed by the Intergovernmental Panel on Climate Change (IPCC) have estimated that about 40 Gton of carbon could be sequestered in agricultural soil over a 50–100 year span by applying improved agricultural practices (Thomson et al., 2008). In many instances, there are also cobenefits (reduced soil erosion, reduced energy costs, improved soil fertility) that provide incentives for terrestrial sequestration practices (Lal, 2004). It is obvious that sequestration practices must aim to maximize the turnover time of SOM in order to be efficient and useful for mitigation purposes.

Decomposition of organic C (OC) can be retarded by different stabilization processes. The interplay between these processes is

complex and requires an understanding of chemical, physical, and biological interactions between organic components and the mineral matrix.

7.2 Modeling of OC Turnover and the Concept of Different SOM Pools in Soils

7.2.1 Modeling of OC Turnover and Stabilization

Turnover models of SOM contribute to our understanding of C dynamics in soils and serve to predict the SOM content under different scenarios. *Turnover time* (τ) is generally defined as the time interval between entering and leaving a reservoir. In carbon biogeochemistry, it is the time interval between assimilation of a C-atom by an ecosystem and the release of the same C-atom as respired CO₂. In many ecosystems (e.g., such as old growth forests), this means that a carbon compound may already be quite old before it enters the decomposition chain in the soil subsystem. Turnover time τ is measured in time units (year). *Carbon stabilization and destabilization* ($\Delta \tau$) is defined as a process that leads to a change in carbon turnover time compared to a reference situation (von Lützow et al., 2006). Prolongation of turnover time, or stabilization, is expressed as

$$\tau_a - \tau_b > 0, \tag{7.1}$$

where

- τ_a is the turnover time after a certain stabilization/destabilization process has occurred
- τ_b is the turnover time before a certain stabilization/destabilization process has occurred

Reduction of turnover time is defined as destabilization:

$$\tau_a - \tau_b < 0. \tag{7.2}$$

In general, SOM is a complex mixture of substances spanning an extreme range of molecular properties so that there is every reason to expect that the organic fragments and decomposition products in soils would differ widely in their radiocarbon content. Here, the problem arises that while SOM may actually be a continuum best represented by a distribution of residence times (Trumbore, 1997), continuous distributions are difficult to constrain with field measurements (Bruun et al., 2010). One strategy to constrain a heterogeneous population is to divide it into sub-fractions that share enough physical or functional features to allow them to be treated as homogeneous. While most contemporary turnover models share this general approach, predicting the long-term stability of carbon compounds in soil remains difficult because of the wide array of processes that may potentially be involved in SOM turnover, including carbon chemistry and its interaction with microbial enzyme systems, mineral soil surfaces, disturbance, and climate (Grandy and

Neff, 2008). Widely used soil carbon models, such as CASA, IBIS-2, CENTURY, and Rothamsted (Jenkinson, 1990; Parton et al., 1994; Randerson et al., 1996; Kucharik et al., 2001), treat SOM as consisting of discrete pools of different turnover times.

The current models subdivide "active" or "labile" pools by assigning different decomposition rate constants to organic input materials (McGill, 1996).

Following Torn et al. (2009), decomposition of a homogeneous reservoir can be treated as a linear, donor-controlled process, that is, the amount of C decomposed is the product of the C stock (C, g C m⁻²), a decomposition rate constant (k, measured in years), and the time interval (Δt , year). The change in soil C stock between one time point and the next (dC/dt) is the difference between the plant inputs (I) and decomposition outputs (kC) over that period, or dC/dt = I - kC, where t =time (year) and I =carbon inputs (g C m⁻² year⁻¹). We also follow Torn et al. (2009) when we define turnover time (τ) as the reciprocal of the decomposition rate constant ($\tau = 1/k$). At steady state $\tau = I/C$ and the soil C stock is the product of inputs and turnover time. See also Torn et al. (2009) for a detailed discussion on the differences underlying the concept of turnover time and mean residence time (MRT).

The "intermediate" or "slow" organic matter pool is typically assumed to turn over on decadal timescales, while "passive" or "inert" organic matter is defined as such organic materials whose turnover happens on centennial and millennial timescales and is largely unaffected by management or disturbance. The formation of intermediate and passive pools in the models is treated as a selective preservation of recalcitrant substances and basically relies on the assumption that the stable fractions are the leftovers from mineralization of plant residues. While the pool structure is likely adequate for capturing soil C dynamics, research over the past decade has found that the controls of partitioning and turnover are poorly parameterized or missing. An important example is reliance on clay content/soil texture to represent the influence of the mineral matrix on soil C storage and decomposability. In the Century model, for example, soil texture influences the decomposition rate of the active SOM pool and the efficiency of SOM stabilization in the slow pool. Fine textures favor slow decomposition rates and greater stability of SOM. However, a recent sensitivity analysis for the Century model suggests that the effect of clay percentage on the rate of C change is not well understood, leading to overestimations of soil organic C (SOC) by an average of 10% (max of 28% in Bricklemyer et al., 2007) following a management change from tillage to no-tillage.

7.2.2 Mechanisms for the Accumulation of Organic Matter in Labile and Stable Pools

The terms "labile" and "stable" are operational and nearly nondescript terms that are used by the biogeochemistry community to indicate major functional differences between the turnover dynamics of SOM pools. They are used for convenience, but do not correspond to measurable, parametric categories. Table 7.1 gives an overview on the different mechanisms that have been

TABLE 7.1 Controls on Turnover Time and Assignment of Timescales

Mechanisms Relevance Timescale Intrinsic recalcitrance of SOM Definition: Molecular characteristics of There is no generally accepted single numerical parameter Protective effects only of transient importance organic substances that influence their to express the degree of recalcitrance, but some consensus in environments with a strong redox degradation by microbes and enzymes exists for some controls on "intrinsic recalcitrance": gradient, oxidation reactions quickly increase Solubility in H₂O (mass per volume); molecular size Dalton) Problem: Characteristics vary solubility, reduce molecular size, and independently, that is, molecular size can Stoichiometric O₂ demand (Mol O₂ per mole substrate) facilitate enzymatic depolymerization be small (would facilitate decomposition) Number of functionally different bonds within the molecule while solubility may be low (would retard Degree of polymerization (number of monomers within decomposition) polymer) Facultative nonutilization of SOM Definition: Specialization of decomposers Facultative nonutilization is a general mechanism of soil-C Mechanism spans whole range from annual to toward different substrates and preservation that can operate on substrates of any millennial timescale, potential for rapid change microhabitats, which leads to a relatively chemical composition. This mechanism can produce a with disturbance and introduction of new biota longer persistence of virtually all kinds of large and stochastically stable C pool with a broad range organic substrates in uninhabited soil spaces of components, without relying on an inert status of the C (Ekschmitt et al., 2008) Spatial accessibility for microorganisms, enzymes and oxygen Mechanism is ubiquitous, but particularly effective in soil Definition: Physical arrangement of soil Typically in the decadal to lower centennial particles may restrict or impede access of environments with high contents of clay and fine silt-sized range. Timescale is related to aggregate size: either decomposers or oxygen or both to OM in small aggregates tends to have slower particles organic substrates turnover than OM in larger aggregates Direct interactions with mineral surfaces Definition: Protective effect that results Mechanism is restricted to such OM that is in direct Longest residence times are consistently from direct attachment to a mineral contact with a mineral surface. A variety of bonding observed in situations where ligand-exchange surface mechanisms are known to operate type bonding mechanisms between protonated Al and Fe surface hydroxyls are

described to control SOM turnover at different timescales; however, most models do not explicitly include those other than selective preservation. There is consensus in the literature that the active pool is composed of fresh plant residues, root exudates, decomposer feces, and of faunal and microbial residues (Smith and Paul, 1990). The selective preservation of recalcitrant compounds leads to a progressive change of residue composition only during initial stages of decomposition. Recalcitrance alone does not explain longer term stabilization of SOM (von Lützow et al., 2006; Marschner et al., 2008). With further decomposition, spatial inaccessibility due to occlusion within macroaggregates and microaggregates (i.e., biogenic aggregation; >250-20 µm) becomes a relevant process of organic matter (OM) stabilization (Angers and Giroux, 1996; Six et al., 2002). Stability of OM increases with decreasing aggregate size and the stabilized OM is dominated by microbial products (Golchin et al., 1997). Analyses of ¹⁴C and ¹³C revealed that OM bound to mineral surfaces can contribute to the intermediate pool in particular in A horizons with high microbial activity and C turnover (Trumbore, 1993; Balesdent, 1996; Flessa et al., 2008; von Lützow et al., 2008). Also, complexation of OM of different recalcitrance with metal ions and sorption of dissolved organic matter (DOM) to mineral soils leads to stabilization within the intermediate pool (Kalbitz and Kaiser, 2008).

Four process groups have been described to contribute to the formation of the passive pool: Abiotic microaggregation by encrustation of clay particles around OM can lead to the formation of very stable clay-OM microstructures (<20 µm) (Oades, 1993). Another important process that can reduce soil OM accessibility is the formation of hydrophobic properties that reduce surface wettability and thus reduce accessibility for degrading enzymes (Goebel et al., 2005). The formation of hydrophobic surfaces is a major factor in aggregate formation and enhances aggregate stability (Bachmann et al., 2008). Interaction with mineral surfaces is a third process that may increase OM stability in the time frame of the passive pool (Anderson and Paul, 1984; Scharpenseel and Becker-Heidmann, 1994; Torn et al., 1997). The quantification and evaluation of the stability of the different binding mechanisms of organo-mineral interactions (e.g., ligand exchange, cation bridging, van der Waals forces) is difficult because often more than one bonding mechanism or stabilization mechanism are operating simultaneously (Kögel-Knabner et al., 2008). For example, OM within organo-mineral associations may be stabilized simultaneously by ligand exchange at edge sites of phyllosilicates, by polyvalent cation bridges due to their permanent loading (Kahle et al., 2002b) and due to the formation of hydrophobic surfaces (Chenu et al., 2000; Doerr et al., 2000). Finally, passive OM is formed by

and smectitic soils

favored, however, centennial and millennial turnover has also been observed in kaolinitic

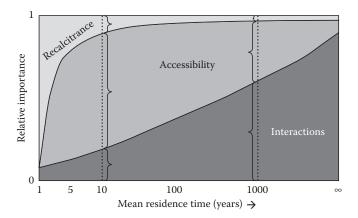

FIGURE 7.1 Current understanding of how the relative contributions of the three major stabilization mechanisms (recalcitrance, accessibility, and interactions) to the protection of organic matter against decomposition change with increasing residence time of organic matter. Only organic matter that is protected by interactions with minerals or physically separated from decomposers (accessibility) achieves long turnover times.

fire (Schmidt et al., 2002). In addition to the selective preservation of these highly condensed aromatic compounds there is evidence that the interaction of black carbon (BC) with minerals, its occlusion particularly in microaggregates and its hydrophobicity are responsible for the high stability of partly degraded charred OM (Brodowski et al., 2007). Figure 7.1 illustrates the notion that the above mechanisms vary in importance for the protection of carbon as a function of residence time.

Some other concepts to explain stabilization within the passive pool have been suggested, but are not convincingly supported by empirical data (von Lützow et al., 2008). The intercalation of DOM into internal phyllosilicate surfaces as proposed by Theng et al. (1986) has not been found to be quantitatively relevant in natural soils. Also, the spontaneous condensation and polymerization of OM as humic material was questioned (Knicker and Lüdemann, 1995; Hedges et al., 2000; Burdon, 2001; Sutton and Sposito, 2005). No direct measurement of OM stabilized by encapsulation in larger hydrophobic molecular complexes as often proposed is found (Schaumann, 2006; von Lützow et al., 2006), while speculations about the potential stabilization effects of organo-organo interactions (Wershaw, 1999; Buurman et al., 2002; Ellerbrock et al., 2005; Kelleher and Simpson, 2006; Kleber et al., 2007) have been revived recently. In addition, aromatic π -systems within organic compounds have the capacity to adsorb to minerals and organic soil and sediment components such as natural organic matter (NOM) and fire-derived BC through specific sorptive forces other than hydrophobic interactions (Keiluweit and Kleber, 2009).

7.2.3 Fractionation Concepts and Isolation of Specific Fractions

Our efforts to improve current models of soil carbon turnover would benefit from a greater ability to assign specific stabilization mechanisms to measurable SOM fractions. To achieve this goal, it is necessary to identify and isolate "functionally different but unique (non-composite) SOM pools with a homogeneous decay behaviour" (Smith et al., 2002; Bruun et al., 2004).

7.2.3.1 Aggregate Fractionation

Aggregate fractionation is based on the separation of free SOM and protected SOM that is occluded in organo-mineral assemblages of different sizes. The different aggregate fractions aim to isolate active from intermediate and passive SOM pools (separation of free SOM from SOM occluded by macro- and microaggregates and SOM in clay microstructures, respectively). Aggregate fractions are obtained by dry or wet sieving and slaking (immersion in water of dry aggregates). Aggregates <20 µm are very stable and are only disrupted by ultrasonic treatment (Oades and Waters, 1991). Aggregates <2 µm even survive ultrasonic treatment (Chenu and Plante, 2006). To identify SOM pools that preferentially stabilize SOM in the longer term, Six et al. (2000) suggested a fractionation scheme of wet sieving and slaking to completely break up macroaggregates while minimizing the breakdown of the released microaggregates (53–250 μ m). In most temperate surface soils, aggregates generally do not break down into primary particles upon slaking but rather into smaller stable units, indicating that the aggregates are arranged in a hierarchical fashion (Tisdall and Oades, 1982; Oades and Waters, 1991). In these soils, macroaggregates (>250 µm) often contain more OM than microaggregates (<250 µm), because the former include microaggregates plus OM serving as an intramacroaggregate binding agent. This may not be the case in tropical soils, where other cementing agents stabilize macroaggegates (Oades and Waters, 1991).

Nearly 90% of SOC in surface soils was found to be located within aggregates (Jastrow et al., 1996) with 20%–40% of SOC as intra-microaggregate SOC (Carter, 1996). The degree of decomposition increases with decreasing aggregate size from macroto microaggregates, as indicated by a decrease of the C/N ratio, plant components or ¹⁴C labeled plant residues (Gregorich et al., 2003), an increase of microbial-derived carbohydrates and the ratio of alkyl/O-alkyl C (Steffens et al., 2009). Angers et al. (1997) observed a redistribution of ¹³C from macroaggregates to microaggregates with time, which clearly indicates that C occlusion in microaggregates only happens after occlusion at the macroaggregate scale. Consequently, microaggregate OM is on average older and in a more decomposed state than macroaggregate OM.

Various studies have shown that turnover times of occluded OM increase with decreasing aggregate size. Turnover times were about 15–50 years for OM stored in macroaggregates (>250 μ m) and 100–300 years for OM in microaggregates (<250 μ m) (Angers and Giroux, 1996; Besnard et al., 1996; Puget et al., 2000; Six et al., 2002; John et al., 2005). It is considered that SOM is stabilized by different aggregate formation processes, biogenic aggregation in macroaggregates, and abiotic clay flocculation in microaggregates. Biogenic aggregation is a relatively transient process within the active and intermediate OM pools and is sensitive to management practices. Occlusion of SOM within clay microstructures (<20 μ m) is operative over long timescales

controlled by pedogenic processes (e.g., weathering of clay minerals, formation of iron oxides and hydroxides) (von Lützow et al., 2006).

7.2.3.2 Particle Size Fractions

Particle size fractionation is based on the concept that SOM associated with particles of different size and therefore also of different mineralogical composition differs in structure and function (Christensen, 1992). While quartz particles that dominate the sand fraction exhibit only weak bonding affinities to SOM, the clay-sized particles (e.g., sesquioxides, layer silicates) provide a large surface area and numerous reactive sites where SOM can be associated (Sposito et al., 1999).

A meta-analysis suggests that in temperate arable top soils about 50%-75% of total OC is associated with clay-sized particles ($<2\mu m$), about 20%–40% with silt-sized particles ($2-63\mu m$) and <10% with sand-sized particles (>63 µm) (von Lützow et al., 2007). However, the generally higher allocation of SOC in smaller particles was not always congruent with a longer turnover time. In the sand fraction, ¹³C turnover times ranged from 0.5 to 374 years, in the silt fraction from 115 to 676 years, and in the clay fractions from 76 to 190 years. The 14C MRT in the silt and clay fraction showed a span of 800-1660 and of 75-4409 years, respectively. Microbial colonization and activity was largely confined to particles coarser than clay (small bacteria such as Escherichia coli are about 1 µm in diameter). Fungal activity is strongest in sand, while bacterial activity is strongest in silt. As demonstrated by the hexose-to-pentose ratios, the coarser fractions are dominated by SOM derived from plant material, while the SOM in the clay fraction is dominated by microbially derived metabolites (Guggenberger et al., 1994). The fine clay fraction $(<0.2 \mu m)$ does not fully follow the general trend of increasing carbon allocation with decreasing particle size. This is also true for the MRT and turnover times, which are shorter and faster, respectively, in this fine fraction than in the coarser clay fraction. The data compiled by von Lützow et al. (2007) show that the proportion of allocated carbon decreased from 30%-50% in coarser clay fractions (0.2-2 µm) to 4%-20% of total OC in the fine clay fraction. This is associated with a lower turnover in fine clay as compared to the coarser clay fraction. The MRT was 130-1741 years (turnover time of 179-277 years) in the coarse clay and MRT 125-352 years (turnover time of 76-190 years) in fine clay. In summary, fractionation by particle sizes provides a rough differentiation between young (active) and older (intermediate and passive) SOM. Slower C turnover rates in clay fractions compared to the sand fraction were explained by a combined action of all three process groups of OM stabilization: the chemical change in OM quality, an increase in spatial inaccessibility (e.g., due to microaggregation) and the adsorption of OM on mineral surfaces. But particle size fractions are not homogeneous in terms of their turnover time and can thus not be used to represent functional pools in turnover models. Several binding mechanisms seem to be responsible for the differentiation of the passive pool, as indicated by the faster turnover of OM associated with the fine clay subfraction compared to OM in the coarse clay subfraction (Laird et al., 2001; Kahle et al., 2003; Wattel-Koekkoek et al., 2003; Kleber et al., 2004; von Lützow et al., 2006).

7.2.3.3 Density Fractionation

Density separation of soils is based on the fact that soil organic materials typically have densities varying from 1.24 to 1.64 kg L⁻¹ (Mayer et al., 2004), while minerals have much higher densities (e.g., quartz is at 2.65 kg L⁻¹). Common procedures separate soil materials in (1) a free light fraction with a density smaller than 1.6 kg L-1, (2) an occluded light fraction, which is disaggregated after sonification, and (3) a residual dense fraction representing organo-mineral complexes tightly adsorbed to mineral surfaces (Golchin et al., 1994a). Density fractionation is popular as a technique to isolate proxies for functional SOM pools, with the generally accepted understanding (Sollins et al., 1984) that the light fraction contains predominantly easily decomposable plant debris while the dense fraction represents the mineral-associated and thus protected parts of OM. The light fraction can contain charcoal in addition to particulate plant litters and the dense fraction sometimes shows signs of rapid incorporation of isotopic labels (Strickland et al., 1992; Swanston et al., 2005). These restrictions have led some workers to use density fractionation mainly as a pretreatment with the main objective to remove "light" particulate OM prior to subsequent investigations of particle-size fractions (Eusterhues et al., 2005) or as a pretreatment for chemical extraction procedures (Bird et al., 2002).

Separating soil samples into multiple density fractions has increasingly been used as a technique to investigate the mechanisms behind OM stabilization and the association of organic materials with the mineral matrix. Golchin et al. (1994b) noted that the organic materials in the dense fraction (>2.0 kg L-1) showed predominantly 13C NMR signals of carbohydrate and aliphatic structures, an absence of lignin and tannin structures and a narrow C:N ratio, leading them to conclude that clay minerals are able to adsorb and protect OM rich in nitrogen, suggesting a microbial origin for this fraction (Golchin et al., 1994b). Baisden et al. (2002) used sequential density fractionation to show a progressive decrease of C/N ratios with simultaneous enrichment of ¹³C and ¹⁵N and decreasing Δ^{14} C with increasing densities in a California soil chronosequence. In line with Golchin et al. (1994b), Baisden et al. (2002) interpreted this phenomenon as suggestive of increasing SOM decomposition with increasing fraction density and increasing age of the mineral-associated OM.

Sollins et al. (2006) hypothesized that sequential density fractionation might remove subsequent layers of organic materials with each fractionation step. Applying sequential density fractionation to a smectitic soil from the Oregon Cascade Range, they observed a "general pattern of an increase in extent of microbial processing with increasing organo-mineral particle density and with increasing soil organic matter turnover time."

Like aggregate and particle size fractionation, the density fractionation allows only for a rough differentiation between active and passive OM. While the free light fraction (<1.6 kg L⁻¹) is a good representation of the active pool (except in soils containing BC), the dense fractions are heterogeneous. Sequential isolation of progressively denser fractions shows trends toward higher nitrogen contents and lower lignin concentrations with increasing density (Sollins et al., 2006). However, the phases separated still contain heterogeneous organic materials and can thus not be equated with functional (active, slow, passive) pools in an unequivocal manner. However, sequential density fractionation has been successfully used to contribute to a mechanistic understanding of carbon turnover dynamics in mineral-organic associations (Golchin et al., 1994b; Baisden et al., 2002; Sollins et al., 2006).

7.3 Recalcitrance as an Index for Intrinsic Organic Matter Quality

7.3.1 Terms and Mechanisms

The term recalcitrance is commonly used when a certain degree of resistance to decomposition is to be conveyed. At present there is a debate about the usefulness of the concept of recalcitrance. Some authors find that the lack of a precise numerical definition for recalcitrance prevents the concept from being useful in support of modeling studies while others consider recalcitrance as a vital control that determines the initial pathways of decomposition. We refer the reader to publications by Kleber (2010) and von Lützow and Kögel-Knabner (2010) for a more detailed discussion of the subject.

Recalcitrance has been defined as the "molecular level characteristics of organic substances that influence their degradation by microbes and enzymes" (Sollins et al., 1996). Throughout this text, we use the term "recalcitrance" as suggested by von Lützow et al. (2006). Several molecular features have been proposed as having the ability to render natural OC compounds refractory, including molecular size (Alexander, 1981), aqueous solubility or polarity (von Lutzow et al., 2006), aromaticity (Campbell et al., 1967), aliphaticity expressed as alkyl/O-alkyl ratio (Baldock et al., 1997), molecular complexity (Bosatta and Angren, 1999), certain N-containing substituents and functional groups (von Lützow et al., 2006), and many others, but these characteristics may vary independently within the same compound. For example, small molecular size is commonly thought to facilitate decomposition, while low aqueous solubility is perceived as an obstacle to decomposition, but molecular size can be small and solubility can be low at the same time, as in benzene.

7.3.2 Plant and Microbial-Derived Compounds

The relative accumulation of recalcitrant molecules leads to a preservation of these components relative to other more easily decomposable components during early stages of litter decomposition. Selective preservation is less important in later stages of decomposition because it was shown that potentially labile organic compounds (polysaccharides and proteins) exhibited

longer turnover times than potentially recalcitrant compounds (lignin, lipids) and turnover of recalcitrant compounds was faster or similar as bulk soil OM turnover (see Marschner et al., 2008 for a detailed discussion). Consequently, primary recalcitrance has been defined for plant litter and rhizodeposits as a function of their indigenous molecular characteristic, and secondary recalcitrance for microbial products, humic polymers, and charred materials (von Lützow et al., 2006).

It has been posited that selective preservation due to recalcitrance of OM is the only mechanism by which soil OC can be protected for long periods of time (Krull et al., 2003). It appears, though, that the chemical structure of organic molecules by itself is not sufficient to account for long turnover times. There is ample evidence that the biotic community is able to degrade any OM of natural origin and that we have no indication for the existence of inert OM components. The relatively rapid cometabolic mineralization of charcoal, for example (von Lützow et al., 2006), demonstrates the ability of microorganisms to degrade even complex and "recalcitrant" structures. Relatively fast turnover rates of lipids and lignin and slow turnover rates of polysaccharides and proteins suggest the importance of protective mechanisms (Marschner et al., 2008). Another concept that is increasingly questioned is the notion that humification reactions create recalcitrant humic polymers. Evidence against spontaneous heteropolycondensation theories is mounting (Hedges et al., 2000; Burdon, 2001; Sutton and Sposito, 2005; von Lützow et al., 2006) as state-of-the-art analytical techniques fail to identify chemically distinct humic substances within SOM (Kelleher and Simpson, 2006; Lehmann et al., 2008). Generally, SOM with turnover times equivalent to the passive pools of established soil carbon models (greater then 50-70 years) was only found in association with minerals (Marschner et al., 2008). Thus, recalcitrance alone cannot explain long-term stabilization and is not the major driving force of passive C pool formation. Selective preservation of recalcitrant compounds is only relevant within the active pool (<10 years) and is of particular importance in horizons with large C contents like in topsoil A horizons. This new view of the role of recalcitrance in the hierarchy of protective mechanisms is reflected in the suggestion by von Lützow et al. (2006), who posit that "recalcitrance is only important during early decomposition and in active surface soils." The "facultative nonutilization of substrates" as a result of the specialization of decomposers (Ekschmitt et al., 2005; Fox et al., 2006; Ekschmitt et al., 2008) explains how organic materials can be left undecomposed even when they are neither recalcitrant nor protected by aggregation or adsorption. This implies a reconsideration of the basic concepts underlying existing compartment and cohort models.

7.3.3 Fire-Derived Organic Matter (Black Carbon)

Because exposure of carbon compounds to heat occurs regularly in natural and anthropogenic environments, BC is ubiquitous in terrestrial systems. BC is commonly considered to

belong to the carbon pool with millennial turnover time, with no role in short-term carbon cycling (Czimczik and Masiello, 2007), but with an important function as a natural means of long-term carbon storage (Lehmann et al., 2008). BC has received much attention for two major reasons. First, a general lack of knowledge of BC loss processes from soils and sediments has been perceived, which hinders a better understanding of fluxes into and out of the Earth's slow cycling carbon pools (Masiello, 2004). Second, sequestration of anthropogenic BC (biochar) into soils combined with bioenergy production has been suggested as a clean energy technology to mitigate climate change that combines the long turnover time of char with its high CEC to maximize benefits (Lehmann, 2007a, 2007b). In both cases, scientific answers and technological solutions require more information on the dynamics of BC in terrestrial environments. The possibility of the existence of more dynamic forms of BC in soils has been raised repeatedly to explain observations of faster than millennial turnover (Bird et al., 1999; Czimczik and Masiello, 2007; Hammes et al., 2008). Once released into the environment, the original surface properties of BC can be affected by "aging" processes caused by interactions with abiotic and biotic soil constituents. At this point, more evidence points to abiotic, "oxidative weatheringlike" alterations than to biotic degradation (Cheng et al., 2006, 2008). However, the extent to which BC is able to persist in the environment is the subject of an ongoing debate.

7.3.4 Carbonaceous Pollutants and Nanomaterials

The intentional and unintentional introduction of synthetic organic chemicals into the environment is a consequence of the rapidly increasing demand for food, materials, and energy of human society. Some of these synthetic chemicals cause problems by affecting nontarget organisms, including humans. A particular concern is associated with the accumulation of persistent chemicals in the food chain. While biouptake of polychlorinated biphenyls (PCB) to toxic levels has been recognized as early as 1968 (Risebrough et al., 1968), the increasing industrial use of organic nanomaterials like fullerenes (e.g., C60) and carbon nanotubes exposes the biosphere to a novel threat of largely unknown dimensions. Fullerenes, which can act as Lewis acids (electron acceptors) despite their inherent hydrophobicity, may exhibit specific interactions with natural soils and sediments due to electron donor-acceptor (EDA) interactions. This has the far-reaching consequence that organic compounds like fullerenes may be able to interact in ways with organic and mineral constituents that deviate from the behavior of other hydrophobic chemicals, creating a large uncertainty about their fate in environmental systems and the timescale for decomposition. There is a clear need for the development of robust methods for the detection and quantification of fullerenes and other carbonaceous nanomaterials in soils and for studies of the controls on their decomposition dynamics in terrestrial environments.

7.4 Stabilization of SOM

Long-term stabilization of labile compounds, especially polysaccharides and proteins shows the importance of active stabilization mechanisms. Some consensus has been reached that the process types that determine long-term stability and lead to long turnover times of SOM (Sollins et al., 1996; von Lützow et al., 2006) are

- 1. Spatial inaccessibility (due to aggregation)
- 2. Chemical (sorptive) interactions with mineral particle surfaces and metal ions

Since these mechanisms were first proposed, much effort has gone into elucidating their relative importance for soil carbon content, that is, how much carbon a given soil can protect against decomposition.

7.4.1 Soil Architecture and Its Effects on C Turnover and Stabilization

The soil matrix is separated into variable-sized compartments such that transfer rates of enzymes, substrates, water, oxygen, and microorganisms can be limited. The input pathways as well as the location of OM within these compartments determine accessibility by the decomposer community. Evolutionary selection toward specialized substrate utilization has provided the decomposer community with the chemical and physical tools to degrade any kind of reduced carbon to its fully oxidized state in CO₂. Specialization of decomposers toward preferred substrates and soil spaces (Ekschmitt et al., 2008) convincingly explains longer persistence of C substrates in nonpreferred soil spaces. In A horizons, OM is derived mainly from plant residues that are mixed into surface soils by tillage or by bioturbation, root residues, and exudates (Balesdent and Balabane, 1996). In subsoils, C input occurs mainly through plant roots and through leaching of dissolved OM. Preferential flow paths of dissolved OM may be considered as "hot spots" in soils, because they permit better nutrient and substrate supply compared to the whole soil matrix (Bundt et al., 2001). The importance of preferential flow paths for C input increases with soil depth. With increasing depth there is less probability for any point in a soil to be located near a preferential flow path or hot spot. This is consistent with the generally greater radiocarbon age of subsoil OM compared to surface soils (Chabbi et al., 2009). Physical barriers due to the wetting resistance and chemical heterogeneity of surfaces, hydrophobic interfaces, and instable wetting fronts cause spatial heterogeneity of soil moisture and spatial inaccessibility for decomposer organisms. Important processes that can reduce soil OM accessibility are occlusion of OM by aggregation and hydrophobicity.

7.4.1.1 Accessibility/Aggregation: Physical Protection

Observations of enhanced SOM mineralization following disruption of aggregates showed long ago that occlusion in aggregates has a retarding effect on SOM decomposition. Protection will be greatest where aggregate stability is high and aggregate turnover is low; thus, aggregation is the stabilization mechanism that

is potentially most susceptible to disturbance. The fact that soil aggregation is a transient property and that aggregates are continually being formed and destroyed (Baldock and Skjemstad, 2000) suggests further that aggregation/accessibility is the stabilization mechanism controlling the size of the slow or intermediate pool of carbon turnover models, but not the dominant control on centennial or millennial turnover. Measured turnover times for carbon protected by aggregates indicate an inverse relationship between aggregate size and carbon turnover time (Skjemstad et al., 1993; Balesdent, 1996; John et al., 2005; Liao et al., 2006) with the highest reported turnover times being in the lower centennial range (200-320 years) and occurring in the smallest aggregates <20 µm. Occlusion at the clay microstructure level (<20 µm) has been attributed to abiotic mechanisms such as the precipitation of Fe- and Al-oxides or hydroxides (Duiker et al., 2003), but in general soil biota are thought to be strongly involved in the process of occlusion. Thus, microbial cells, secretions, root exudates, and faunal mucus act as cementing agents and are at the same time occluded within microaggregates (von Lützow et al., 2006).

Theories of physical protection (Jastrow et al., 2007) take the presence of old, microbial-type organic materials in very small aggregates as evidence that the OM associated with microaggregates may not only be physically protected but also highly humified and biochemically recalcitrant (Liao et al., 2006). However, if there are no recalcitrant, polymeric humic macromolecules, as suggested by an increasing number of authors (Sutton and Sposito, 2005; Kelleher and Simpson, 2006; Marschner et al., 2008), then we are forced to develop alternative scenarios to explain the mechanisms of long-term stabilization of energy-rich microbial residues or microbial products in small aggregates.

With the assumption that microbiota have an active role in the creation of long-lasting microstructures, we simultaneously infer that operationally defined "passive" soil C pools may at least partially consist of thermodynamically labile C. If confirmed, then this would mean that it is not the thermodynamic properties of OC itself, but rather the association of C with mineral surfaces that provides long-term stabilization. In the model proposed by Lehmann et al. (2007; Figure 7.2), microaggregate formation is initiated by the accumulation of microbial products on clay particle surfaces, not by the occlusion of organic debris between primary particles, a view that is in line with the TEM observations of Chenu and Plante (2006) and the STXM observations by

Wan et al. (2007; Figure 7.3). These authors report that many of so called "clay particles" were in fact nanometer- to micrometersized microaggregates in which OM was encrusted by minerals. They concluded that these very small microaggregates are major sites of OM stabilization "both by adsorption and by entrapment of organic matter," as demonstrated in Figure 7.4. This concept is supported by measurements of microbial sugars in contact with pedogenic oxides by Spielvogel et al. (2008) and by contemporary theories about the structure of OM coatings in contact with mineral surfaces (Wershaw et al., 1996; Kleber et al., 2007; Bachmann et al., 2008). Further support comes from recent assessments and reports showing that carbon associated with mineral surfaces has a distinct composition related more to microbially processed OM than to plant related compounds (Grandy and Neff, 2008; Spielvogel et al., 2008). Figure 7.5 gives an example for the initiation of aggregation by microbial cells.

7.4.1.2 Hydrophobicity

Hydrophobicity reduces surface wettability and thus the accessibility of OM for microorganisms. This is supposed to result in decreased decomposition rates, as the absence of water directly restricts the living conditions of microorganisms (Goebel et al., 2004; Jandl et al., 2004).

Persistent hydrophobicity has often been attributed to the presence of a coating on soil particles consisting of adsorbed fatty acids (Doerr et al., 2000) that have been identified as mainly plant-derived long-chain compounds (n-C22:0 to n-C34:0) (Jandl et al., 2004). Many other studies have attributed hydrophobicity to the presence of OM, examples are reports by Woche et al. (2005) on hydrophobicity in sandy forest soil, studies by de Jonge et al. (1999) who found the smallest particles (<63 μ m) exhibited the highest hydrophobicity, and the work of Chenu et al. (2000) on the impact of OM on the wettability of clays. Hydrophobic properties have been measured for SOM: humic acids, OM bound to clay minerals, plant debris, and microbial residues (Chenu et al., 2000; Doerr et al., 2000). The presence of persistent hydrophobic organic coatings alone, however, does not explain the observed reversibility and *seasonal* changes in water repellency.

Horne and McIntosh (2000) attributed seasonal changes in soil wettability to OM structure, specifically, to the existence of multiple, functionally different layers of OM on sandy grains. In their model, an inner layer of more hydrophobic compounds is covered by a layer

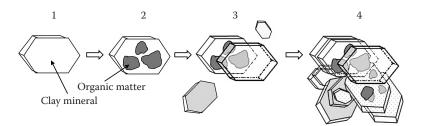

FIGURE 7.2 Model of the formation of free stable microaggregates by, first, the development of an organic coating on a clay minerals and then the physical occlusion of the organic coating (and other entrapped organics by a second mineral). of amphiphilic compounds. When the soil is wettable, the outer surface is well hydrated and the hydrophobic material is effectively screened. Repellence occurs as the soil dries, when the hydrophobic compounds making up the inner layer are more exposed.

The view that soil OM consists largely of relatively small amphiphilic organic molecules has steadily gained ground

over the last decade (Wershaw, 1999; Piccolo, 2001; Sutton and Sposito, 2005). Kleber et al. (2007) combined previous evidence in a suggestion of a zonal model of mineral–organic associations and used this basic assumption to derive a multilayered structure for OM accretions on mineral surfaces (Figure 7.6). This model can explain both seasonal (i.e., moisture dependent) as well as permanent hydrophobicity, where the latter would result from a loss of the two outer layers (Figure 7.6) of amphiphilic organic molecules.

In addition to the direct effect of hydrophobic soil OM properties on microbial accessibility, hydrophobicity at the same time enhances aggregate stability and thereby also contributes to the occlusion of OM as a stabilizing mechanism. Goebel et al. (2005) determined CO₂-efflux from aggregates and homogenized soil and found evidence for both mechanisms, that is, stability of hydrophobic OM itself and enhanced stability of OM occluded in aggregates due to hydrophobic aggregate surfaces. More empirical data about the direct effect of hydrophobicity on degradability of OM are necessary.

7.4.2 Organo-Mineral Interactions

7.4.2.1 The Paradigm of Mineral Control

Organo-mineral interactions, or the protection of OM against decomposition through association with mineral surfaces, have received increasing attention over the past two decades and have been identified as the most likely mechanism to achieve long-term, that is, centennial or millennial, protection of OM (Kögel-Knabner et al., 2008).

Among the first to investigate the effects of clay mineralogy on the turnover of SOM were Allison et al. (1949), who studied the decomposition of added corn straw in an incubation experiment. After 1 year, they recovered 23% of added carbon in the unamended soil substrate. With 10% kaolinite, 10% "soil clay," and 10% bentonite added to the "soil substrate," they recovered 26%, 33%, and 41%, respectively, of the added carbon. Early experimental evidence such as the work of Allison et al. (1949) has led a variety of authors (Goh, 1980; Tate and Theng, 1980; Oades, 1989) to suggest that the impact of clay on C stabilization will change as a function of clay mineralogy.

SOM in fine silt and clay fractions has longer turnover times than OM in other soil OM fractions. Kalbitz et al. (2003) showed that sorption of soluble OM to subsoil material (Bw horizon) reduced OM mineralization to less than 30% compared to mineralization in soil solution. A detailed mechanistic understanding of why sorption to soil minerals reduces decomposition rates is lacking and is complicated by artifacts in the experiments. Chenu and Stotzky (2002) suggest that small molecules sorbed to mineral surfaces cannot be utilized by microorganisms unless they are desorbed so that they can be transported into the cell. But they also caution that it is difficult to demonstrate the unavailability of adsorbed molecules because desorption can occur through microbial secretions during the experiments. The adsorption of macromolecules is considered to be associated with conformational changes that render macromolecules unavailable

to the action of extracellular enzymes (Theng, 1979; Khanna et al., 1998). But as shown by Demaneche et al. (2001) degradation can also be hindered by adsorption of the relevant enzyme to clay minerals rather than by adsorption of the substrate. There is clearly a need for a better understanding of the effect of adsorption on OM decomposition mechanisms and rates.

Long-term protection of organic molecules by sorptive interactions is limited to those organic materials directly bonded to the protecting mineral surface, which is of a finite size (Kleber et al., 2005). Abundant evidence that substantial parts of mineral surfaces are not covered by OM (Ransom et al., 1998; Arnarson and Keil, 2001; Mayer and Xing, 2001; Kahle et al., 2002a) has led to the insight that organic materials must be stacked or clustered on mineral surfaces (Kaiser and Guggenberger, 2003) in small patches with some vertical extension. Such a multilayer architecture of organic coatings on mineral surfaces suggests that only the inner layer of organic molecules is able to participate in direct, strong mineral-organic interactions (Kleber et al., 2007). The degree of saturation of protective sites should thus affect the preservation potential of newly added carbon to the soil. Consequently, there should be a greater potential for OM preservation in the subsoil where the OM saturation of mineral particles is small.

Clay-sized particles like layer silicates (<2 µm), sesquioxides (crystals 5-100 nm), short-range ordered Fe-oxides (3-10 nm) and amorphous Al-oxides (<3 nm) provide the most significant surface area onto which OM can adsorb (Jahn et al., 1992; Schnitzer and Kodama, 1992; Torn et al., 1997; Percival et al., 2000; Basile-Doelsch et al., 2005; Eusterhues et al., 2005; Kleber et al., 2005; Rasmussen et al., 2005; Basile-Doelsch et al., 2007; Kaiser and Guggenberger, 2007; Spielvogel et al., 2008). Mineral reactivity, rather than mineral texture, consistently serves as a better predictor of the residence time and turnover time of stable SOC, and can be associated with two to threefold differences in total soil C storage (Torn et al., 1997; Kahle et al., 2004; Kleber et al., 2004, 2005; Masiello et al., 2004; Mertz et al., 2005; Mikutta et al., 2005; Rasmussen et al., 2005, 2006, 2007). The extent to which microbial metabolites produced from decomposing plant residues are stabilized in different soils is controlled by specific surface area (SSA) provided by clay minerals (Saggar et al., 1996). The OM contents of coarse and fine clay subfractions depend on the mineralogy and, more specifically, on the surface reactivity of the mineral constituents. In the coarse clay fraction, silicate mineral surfaces (montmorillonite > vermiculite > illite > kaolinite) are more important for carbon storage than Fe oxides, which dominate in fine clay fractions and in acid subsoils (Anderson et al., 1981; Kahle et al., 2003; Kleber et al., 2004). Significant debate surrounds the question whether the abundance of certain mineral phases might serve to predict the turnover time of OM in soils. It is noteworthy that no field study has been published to date that indicates a role for unweathered primary minerals in controlling carbon turnover. Mineralogical effects on carbon stabilization have been reported exclusively for secondary minerals, particularly such with abundant hydroxylated surfaces. Examples include Fe oxides (Kaiser and Guggenberger, 2007; Kögel-Knabner et al., 2008),

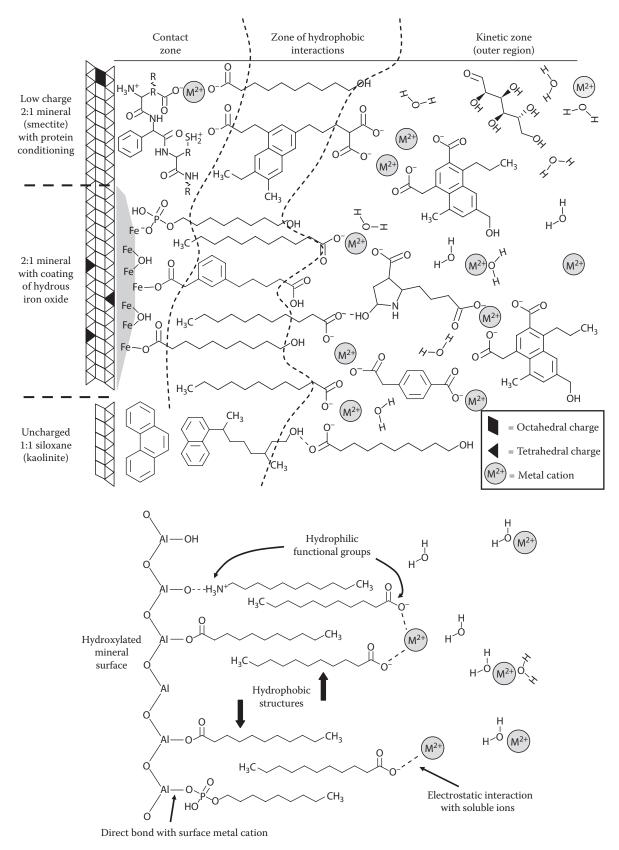

FIGURE 7.6 Multilayer model of amphiphilic organic fragments attached to mineral surfaces. (Reproduced with kind permission from Springer Science+Business Media: Biogeochemistry, A conceptual model of organo-mineral interactions in soils: self-assembly of organic molecular fragments into zonal structures on mineral surfaces, 85, 2007, 9–24, Kleber, M., P. Sollins, and R. Sutton. Copyright Springer Verlag GmbH. With permission.)

Al-rich imogolite type materials (Percival et al., 2000; Basile-Doelsch et al., 2005, 2007), short-range ordered Al hydroxides (Rasmussen et al., 2005; Spielvogel et al., 2008), and poorly crystalline materials in general (Jahn et al., 1992; Schnitzer and Kodama, 1992; Torn et al., 1997; Kleber et al., 2005). Considering the often conflicting reports about the efficacy of individual mineral species for the protection of OM against decomposition, it has become increasingly apparent that the same mineral surface type may function differently in different pedogenic environments, as a result of variations in pH, OM chemistry, cation availability, and numerous other environmental controls.

7.4.2.2 Types of C and N in Organo-Mineral Associations

In situ investigations show that the proportion of the mineral-bound OM and its ¹⁴C age generally increase with soil depth. Stabilization by organo-mineral interactions operate at long-term scales and dominate during late decomposition phases and in subsoils (Kögel-Knabner et al., 2008).

Little information is available on the relationship between mineralogy and the chemistry of bound OM. Kögel-Knabner (2000) found that OM in organo-mineral associations of fine fractions and loamy soils has a higher contribution of bacterial polysaccharides whereas mineral-associated OM in acid sandy soils is more aliphatic. Kaolinite-associated OM from grassland and shrub surface soils was enriched in polysaccharide products, whereas smectite-associated OM, supposedly in interlayer spaces, was enriched in aromatic compounds (Wattel-Koekkoek et al., 2001). Laird et al. (2001) attributed differential carbon storage in clay subfractions to a shift in mineral composition from coarse to fine clay. The coarse clay fraction had stronger carboxyl and O-alkyl 13C-NMR peaks and smaller concentrations of extractable amino acids, fatty acids, monosaccharides, and amino sugars than OM associated with the fine clay fraction (Laird et al., 2001; Kahle et al., 2003). Kleber et al. (2004) and Schöning et al. (2005) have found evidence for selective stabilization of O-alkyl C especially by interactions with pedogenic oxides on mineral surfaces within the coarse-clay subfraction. Ligand exchange might be the binding mechanism. In contrast, alkyl C and aromatic C responded to the duration of fertilizer deprivation, but were indifferent to mineral surface reactivity (Kleber et al., 2004). Generally, the OM associated with soil minerals has a low C:N ratio (often around 8-12). This is attributed to the association of mainly proteins and peptides (Knicker, 2004; Kleber et al., 2007; Rillig et al., 2007), but to a smaller extent also of DNA (Pietramellara et al., 2009) with the mineral phase.

7.4.2.3 Phyllosilicate Clay Minerals

Phyllosilicates pose an interesting challenge in this context because it is often unclear whether they function as adsorbents for OM or if they merely represent physical barriers between enzymes and SOM. This is illustrated by the fact that clay content often correlates with SOM content, but not with turnover time (Kleber et al., 2005). Organic anions are repelled from negatively charged surfaces in soils, but binding occurs when

polyvalent cations are present on the exchange complex. Unlike Na+ and K+, polyvalent cations are able to maintain neutrality at the surface by neutralizing both the charge on the negatively charged surface (e.g., in clay minerals) and the acidic functional group of the OM (e.g., COO-) and thus act as a bridge between two charged sites. The major polyvalent cations present in soil are Ca2+ and Mg2+ in neutral and alkaline soils and hydroxypolycations of Fe3+ and Al3+ in acid soils. The Ca2+ ions do not form strong coordination complexes with organic molecules, relative to Fe³⁺ and Al³⁺. For a long-chain organic molecule with multiple functional groups, multiple points of attachment to the clay particle (segment-surface contact) on permanent charge sites of layer silicates are possible. Microbially secreted polysaccharides frequently carry a negative charge due to the presence of uronic acids that adsorb strongly to negatively charged clay surfaces through polyvalent cation bridging (Chenu, 1995). The bonding efficiency of OM on phyllosilicates by cation bridges is weaker compared to ligand exchange on Al and Fe hydroxides (Benke et al., 1999; Kaiser and Zech, 2000).

In the case of hydrogen bonds, a hydrogen atom with a positive partial charge interacts with partially negatively charged O or N atoms. Hydrophobic interactions are driven by the exclusion of non-polar residues (e.g., aromatic or alkyl C) from water to force the non-polar groups together. These interactions arise from enthalpy and entropy changes associated with water—water, aromatic compound—water, and sorbent—water interactions, as well as from van der Waals forces between apolar moieties and sorption sites. van der Waals forces are nonspecific attractive forces between uncharged molecules and are superpositions of London dispersive energies, Debye energies, and Keesom energies (Schwarzenbach et al., 2003)

Non-expandable layer silicates (e.g., 1:1 layer silicates like kaolinite) or quartz particles without layer charge and without interlayer spaces exhibit only weak-bonding affinities. The negative charge on the siloxane surface of other clay minerals depends on the type and localization of the excess negative charge created by isomorphic substitution. In the absence of a layer charge, a siloxane surface may be considered uncharged. Uncharged, but polar polysaccharides and extracellular enzymes or other proteins can form linkages via hydrogen bonding or van der Waals forces because of the presence of hydroxyl and other polar groups in the molecule (Quiquampoix et al., 1995). Their typically high molecular weight offers a large number of potential surface-segment contacts and thus strong binding between uncharged polysaccharides and clays can be established (Theng, 1979). Hydrophobic interactions become more favorable at low pH when hydroxyl and carboxyl groups of OM are protonated and the ionization of carboxyl groups is suppressed. Bonding interactions of apolar aromatic ring structures have long been considered as restricted to energetically weak, nonspecific, hydrophobic interactions (Chiou et al., 1979; Karickhoff, 1984; Mader et al., 1997; Schwarzenbach et al., 2003). Over the last decade, an increasing number of authors have suggested specific (i.e., directed) and energetically stronger adsorption mechanisms between aromatic π -systems of organic compounds and sorption sites at mineral surfaces. In particular, noncovalent EDA interactions of aromatic compounds with mineral surfaces have been proposed, including cation– π interactions (Zhu et al., 2004; Mueller et al., 2007), n– π EDA interactions (Haderlein and Schwarzenbach, 1993; Haderlein et al., 1996; Weissmahr et al., 1998), and hydrogen– π interactions (Ringwald and Pemberton, 2000). While these observations suggest that attachment of aromatic SOM to mineral surfaces may involve forces that are stronger than those currently assumed, the quantitative role of EDA interactions for the sorptive preservation of NOM in mineral–organic associations remains to be investigated (Keiluweit and Kleber, 2009).

7.4.2.4 Pedogenic Oxides

It is widely assumed that the energetically strongest associations between OM and mineral surfaces involve the mechanism of ligand exchange between carboxyl groups of OM and hydroxyl groups at the surfaces of mineral phases. Complexation of OM on mineral surfaces via ligand exchange increases with decreasing pH with maximal sorption between pH 4.3 and 4.7, corresponding to pK_a values of the most abundant carboxylic acids in soils. Therefore, ligand exchange between reactive inorganic hydroxyls (OH-groups of Fe- Al- Mn-oxides and edge sites of phyllosilicates) and organic carboxyl and phenolic-OH groups is restricted to acid soils rich in minerals with protonated hydroxyl groups. The sorptive strength of hydroxyl-bearing phases, like Fe-(hydr)oxides and poorly crystalline aluminosilicates increases with decreasing pH (Gu et al., 1994, 1995) and will therefore be particularly relevant in profoundly acidic soils. Kleber et al. (2004) showed that singly coordinated, reactive OH-groups on Fe- Al-oxides and at edge sites of phyllosilicates, which are able to form strong bonds by ligand exchange, are a measure of the amount of OM stabilized in soils in organo-mineral associations. Sorption occurs preferentially at reactive sites such as edges, rough surfaces or micropores (e.g., edges of illite particles where amphoteric Al-OH groups are exposed, crystal surfaces of Fe-oxyhydroxides with singly coordinated OH- groups). Kaiser and Guggenberger (2003) hypothesized that the molecules adsorbed first might be strongly stabilized by multiple ligand attachments. At larger surface loadings, sorption can then take place with fewer ligand attachments involved, which leaves parts of the molecule not attached to the surface and thus renders them more susceptible to degradation.

Investigating correlations between iron oxide contents and OM contents, Wagai and Mayer (2007) discovered that Fe oxides may be critical for OC storage, but likely not via a direct sorption mechanism. A physical role of nano-sized iron oxide particles in carbon stabilization is also suggested by the correlation between crystalline iron oxides and oxidation resistant OM reported by Mikutta et al. (2006), who found that in soils with low contents of poorly crystalline pedogenic oxides, stable OM can be correlated with much less sorptive, crystalline Fe-oxide forms.

7.4.2.5 Allophane and Imogolite

High OM contents are typical for soils derived from volcanic ash (Andosols), containing poorly crystalline aluminosilicates like allophane and imogolite. The striking ability of poorly crystalline aluminosilicate mineral matrices to contribute to soil carbon retention

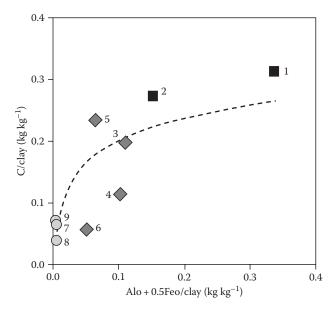

FIGURE 7.7 Soil organic C stored per unit mass of clay as a function of clay composition (Alo + ½Feo = acid oxalate–extractable Al and Fe, index for the abundance of poorly crystalline mineral phases). Values are amounts per square meter and 1 m depth. (Reproduced from Kleber, M., and R. Jahn. 2007. Andosols and soils with andic properties in the German soil taxonomy. J. Plant Nutr. Soil Sci. 170:317–328. Copyright Wiley-VCH Verlag GmbH & Co. KGaA. With permission.) Black squares are andosols (1 = Silandic Andosol, 2 = Aluandic Andosol); grey diamonds are Cambisols and Luvisols (3 = Dystric Cambisol; 4 = Aluandic Luvisol, 5 = Endoskeletic Cambisol, 6 = Orthidystric Cambisol) and circles are Tschernozemic soils (7 and 8 = Haplic Chernozems, 9 = Haplic Kastanozem).

can be illustrated by comparing the OC contents of Andosols with those of other mineral soils (Figure 7.7). On a global scale, Andosols have mean OC contents of 25.4 kg m⁻² in the upper 100 cm (Batjes, 1996), which makes them the most carbon-rich FAO-UNESCO soil unit (organic soils = Histosols excluded). In addition to high OM contents, soils with significant proportions of poorly crystalline minerals also tend to have particularly long OM residence times compared with other soil taxa (Kleber et al., 2005).

Different mechanisms are being discussed to explain high OM storage and long OM residence times in soils containing poorly crystalline aluminosilicate phases:

- 1. Allophane and imogolite contain both permanent charge and surface hydroxyl groups (Harsh et al., 2002). Their charge characteristics are such that imogolite and Al-rich allophane tend to impart positive charge in acid soils, while Si-rich allophane may be either positively or negatively charged depending on soil pH (Harsh, 2000). The resulting ability to form energetically strong ligand exchange type bonds combined with large SSAs (Harsh et al., 2002) allows OM to form lasting sorptive associations with poorly crystalline aluminosilicates.
- 2. Unit particles of allophane tend to coagulate in masses of small spheres varying from 3.5 to 5 nm in diameter. Linear assemblages of these particles may combine into secondary floccules, forming microaggregates that render soils highly

porous (Harsh et al., 2002). The preferential formation of aggregates in the fine silt size range (1–10 μm ; Buurman and van Doesburg, 2007) creates microcompartments with the potential to physically protect OM trapped in the coagulation process. As metastable, poorly crystalline aluminosilicates can only persist in relatively moist soils, it has also been hypothesized that microaggregation may induce anoxic conditions in water saturated microenvironments, thereby impeding OM decomposition (Buurman et al., 2007).

3. Several other modes of OM preservation other than sorptive protection and physical protection have been suggested to operate in soils containing poorly crystalline aluminosilicates. Among these are aluminum toxicity to microorganisms (Tokashiki and Wada, 1975); sorption of degradation enzymes to active Al and Fe (Tate and Theng, 1980), or phosphorus deficiency of decomposer microorganisms caused by high P-retention (Brahim, 1987). However, Buurman et al. (2007) find that there is no conclusive evidence of the relevance of these processes under field conditions, and Scheel et al. (2008) refuted the notion of Al-toxicity in favor of an Al-OM precipitation mechanism. The latter notion of unrestricted microbial activity is supported by abundant reports that OM in close contact with aluminosilicate surfaces consists of microbially processed material (Rasmussen et al., 2005; Buurman et al., 2007), but exhibits a relatively old radiocarbon age (Rasmussen et al., 2005; Sollins et al., 2006).

7.4.2.6 Interactions with Metal Ions

In comparison with the chemistry of metal binding, less information is available about the effect of metal binding on soil OM stability or about the mechanisms involved. Metal ions that have been considered as potentially stabilizing for soil OM are Ca^{2+} , Al^{3+} , and Fe^{3+} and heavy metals.

The earliest evidence for the stabilizing effect of Ca^{2+} ions on soil OM was given by Sokoloff (1938). Since then, several other studies have shown similar effects of Ca^{2+} ions on the mineralization of soil OM and its solubility (Muneer and Oades, 1989) and the large OM content of calcareous soils is also attributed to the effect of Ca^{2+} ions (Oades, 1988).

There is general consensus that the interaction of soil OM with Al and Fe is the main reason for the stability of soil OM in Podzols (Lundström et al., 2000; Zysset and Berggren, 2001; Nierop et al., 2002). However, this conclusion is mainly based on indirect evidence and experimental data on the stability of OM-Al and -Fe complexes is scarce. The Al/C ratio of DOM seems to be an important parameter for its stability against microbial decomposition. In long-term incubation studies, Schwesig et al. (2003) showed that for natural DOM, Al/C ratios >0.1 increased the half-life of the stable DOM fraction up to fourfold.

For Al (and to a lesser extent for Fe), the inhibitory effect of heavy metals on soil respiration and the subsequent accumulation of soil OM has been shown in numerous field and laboratory studies (Tyler et al., 1989; Giller et al., 1998). The concentrations of heavy metals needed to induce retardation of soil respiration often varied by one to three orders of magnitude, depending on experimental and site conditions and on the metal considered. The accumulation of soil OM in the vicinity of heavy metal emission sources, like smelters, in comparison with unpolluted sites is well documented (McEnroe and Helmesaari, 2001; Johnson and Hale, 2004).

The effects of metals on OM stabilization are still poorly understood and difficult to differentiate. Changes in substrate quality by complexation with metals, direct toxic effect of metals on soil microorganisms, and direct effects of metals on extracellular enzymes have all been described. Changes in molecular size, charge, and steric properties of soil OM induced by metal complexation will likely decrease its accessibility to soil enzymes (McKeague et al., 1986) and thereby reduce their availability as microbial substrates. Evidence for such a mechanism is only available from studies with simple model substances. Aluminum complexes of citrate and oxalate in soils were more stable in comparison with the free compounds, but Al effects on degradation under field conditions were less convincing than in the laboratory (Jones et al., 2001). Similar findings with effects in vitro, but fewer effects under soil conditions were reported for Cu and Zn on citrate degradation (Brynhildsen and Rosswall, 1997).

DOM in soils can be precipitated by metal ions and the precipitated DOM can be more stable than the DOM remaining in solution. Larger DOM molecules are precipitated preferentially, while smaller molecules stay in solution (Römkens and Dolfing, 1998; Blaser et al., 1999; Nierop et al., 2002; Schwesig et al., 2003). Evidence for soil OM stabilization by metal ion interactions is described, but general conclusions on their quantitative relevance in soils are difficult to draw. The mechanisms and their effects depend on concentrations and binding forms, and are specific for each element. Often it is difficult to separate the complexing effect of metal cations (Ca, Mg, Al, Fe) from their ability to form cation bridges. Systematic studies and comparisons of the mechanisms are necessary to resolve this puzzle.

7.4.2.7 Minerals as Catalysts

The role of abiotic catalysis reactions is among the most enigmatic and least understood aspects of OM turnover. The central difficulty in assessing the role of abiotic catalyses is that it can facilitate both synthesis reactions (Shindo and Huang, 1982, 1984; Huang and Hardie, 2009) and degradation processes (Rima et al., 2005, Huang and Hardie, 2009). The situation is complicated by the fact that numerous mineral phases are capable of acting as catalysts. However, these mineral phases routinely occur together at the same time in the same soil, and to date, no systematic study has investigated the simultaneous contribution of abiotically catalyzed syntheses and degradation processes for the persistence and stability of OM in a given soil environment. The situation is further confounded by the fact that traditional concepts viewing humic substances as polymeric, macromolecules are increasingly called into question (Piccolo, 2001; Sutton and Sposito, 2005; Kelleher and Simpson, 2006). Thus, while numerous laboratory experiments (see Jokic et al. 2004 and references therein) have confirmed the general ability of mineral phases to facilitate polymerization reactions of organic monomers, the mechanistic relevance of abiotic catalyses and the quantitative importance of its products for carbon turnover processes in natural soil environments remain to be demonstrated. A detailed description of the concept is given by Huang and Hardie (2009).

7.5 Outlook

Evidence is accumulating that the role of the mineral matrix in carbon stabilization needs to be viewed in a new light. In the past, the effect of mineralogy on SOM turnover has typically been viewed as a matter of variations in surface reactivity, and many are the adsorption studies that illustrate the differential abilities of mineral surfaces to function as sorbents for organic compounds (Kaiser and Zech, 2000; Kahle et al., 2004; Mikutta et al., 2007). Stabilization by organo-mineral interactions operates at long-term timescales and dominates during late decomposition phases and in subsoils (Kögel-Knabner et al., 2008). Pedogenetic processes of mineral formation control the strength of bonding and the amount of SOM associated (Percival et al., 2000; Spielvogel et al., 2008). Sorptive interactions can provide strong and long-lasting mineral-organic bounds, but are limited by the finite size of the reactive mineral surface area available (Hassink, 1997; Kleber et al., 2005; Eusterhues et al., 2005). Additionally, there are further limiting requirements in terms of pH, cation availability, and matching organic functional groups (Gu et al., 1995; Mikutta et al., 2007). The importance of certain mineral phases for OM stabilization is easiest shown for acidic subsoils, where they are strong sorbents (Kleber et al., 2005), but is not as convincing in many topsoils (Eusterhues et al., 2005). Iron oxides, for example, can be strong sorbents for OM in one soil and be negatively correlated with OM content in another (Kahle et al., 2002b).

But differences in mineralogy are not just differences in surface chemistry. As minerals are either weathered into fragments or crystallize from solution, they vary in shape and size, kinetic and thermodynamic stability, abundance and extent of reactive surfaces. Consequently, differently sized specimens of the identical mineral cannot be considered constant in their ability to provide reactive surfaces, their ability to serve as physical barriers or as suppliers of dissolved cations, which in turn may act as complexing and/or precipitating agents (Masiello et al., 2004; Schwertmann et al., 2005). Kaolinites, for example, often have an uncharged basal siloxane plane, but can carry reactive hydroxyls on their edges. It follows that a kaolinite crystal with a large basal extension but of shallow height will function differently than a kaolinite crystal of small basal extension but stacked up high.

In acid subsoils, microporous oxide phases efficiently stabilize OM by ligand exchange while more than one bonding mechanism may operate in neutral soils (Kahle et al., 2003). Over the past 10 years, it became evident that pedogenetic processes of mineral formation control the strength of bonding and the

amount of OM sorbed (Spielvogel et al., 2008). Surface coverage of OM on mineral surfaces was found to be discontinuous and SSA was shown to be not always a good predictor for C stabilization (Kaiser and Guggenberger, 2003). Attempts to reconcile these observations include conceptual models that describe the spatial orientation of organo-mineral interactions under different OC contents or a self-assembly of OM into multilayered structures on mineral surfaces (Ellerbrock et al., 2005; Kaiser and Guggenberger, 2007; Kleber et al., 2007).

Although the process groups leading to SOM stabilization namely, selective preservation of recalcitrant compounds, spatial inaccessibility to decomposer organisms and interactions of OM with minerals and metal ions as well as the factors controlling them—have been identified, a challenge in future research is to describe the process mechanisms quantitatively and to evaluate the relative importance of the different stabilization mechanisms in different soils. Past research has established that the interplay of constructive (OM accumulation) and destructive (mineral weathering and cation release) pedogenetic processes determines the types and strengths of bonding interactions at the mineral-organic interface and ultimately the amount of OM sorbed. Considering that the stabilization potentials of soils for OM are site and horizon specific, we identify the need for better ways to link key stabilization mechanisms to pedogenetic processes.

8.1 Introduction

Trace elements may be present in solution with positive or negative charges and in different redox states. They occur predominantly in cationic form (Pb, Cu, Zn, Ni, Cd, Hg, Cr(III), Co), but some are present in anionic form (As, Se, Cr(VI), Mo, and B). Heavy metals and metalloids have critically important biological effects, both beneficial and harmful. In trace amounts, many of these elements (e.g., Cu, Zn, Co) are essential to living organisms, but they become poisonous when their concentrations in the environment and in organisms are sufficiently high. Some elements (e.g., Hg and Pb) are not known to perform any essential biochemical functions and then are injurious or lethal to living organisms even at very low ambient concentrations (Jackson, 1998). Due to industrial development and disposal activity, trace elements are considered to be among the most important environmental contaminants that affect all ecosystem components in natural environments. Concerns about these contaminants are justified in view of the evidence that trace elements are continually accumulating in the food chain (Iskandar and Kikham, 2001).

Characterizing the factors that affect the mobility of metals and metalloids in soil is of paramount importance. Because soils are heterogeneous, heavy metals and metalloids can be involved in a series of complex chemical and biological interactions including sorption—desorption reactions, precipitation and dissolution, oxidation—reduction, and solution and surface phase complexation. The heterogeneous nature of the different soil constituents adds further complexity to the interactions of heavy metals and metalloids in the soil (Selim and Sparks, 2001).

In soil environments, sorption-desorption reactions as well as chemical complexation with inorganic and organic ligands and redox reactions, both biotic and abiotic, are of great importance in controlling metal bioavailability, leaching, and toxicity. These reactions are affected by many factors, such as pH, nature of the sorbents, presence, and concentration of organic and inorganic ligands, including humic and fulvic acid, root

exudates, microbial metabolites, and nutrients (Kabata-Pendias and Pendias, 2001; Huang and Germida, 2002; Violante et al., 2002; Sparks, 2003; Kabata-Pendias, 2004; Huang and Gobran, 2005; Violante et al., 2008).

In this chapter, we highlight the impact of physical, chemical, and biological interfacial interactions on the transformation, and mobility of metals and metalloids in soil. Special attention is devoted to (1) the sorption/desorption processes of metals and metalloids on/from soil components and soils; (2) their precipitation and reduction—oxidation reactions in solution and onto the surfaces of soil components; (3) their chemical speciation, fractionation, and bioavailability; and (4) their transfer to plants.

8.2 Solution Complexation Reactions of Metals in Soils

The soil solution is the medium through which metals and metalloids are taken up, either actively or passively by plant roots and microbial cells. The soil processes (adsorption-desorption, complexation, precipitation-dissolution, or oxidation-reduction) control solution composition. Microorganisms and organic matter also have an important role in influencing the composition of the soil solution. Microorganisms breakdown organic matter and produce new biochemical reaction products. Soluble organics originate from organisms, including exudates from plant roots and soil microorganisms. The concentrations of these organics in the soil solution are more dynamic and more variable than the inorganic constituents. Enzymes (Bollag et al., 1998) and abiotic catalysts (Huang and Hardie, 2009) are important factors that affect the rate of formation and transformation of organic components. Organic matter, especially low-molecular-mass organic acids (LMMOAs), greatly enhances the solubility and mobility of metals in soil environments. In particular, metal complexation reactions with ligands play a significant role in controlling the chemical reactivity, bioavailability, and toxicity of metals in soil solution. The most important complexing functional groups of soil organic matter can be classified based on their affinity for hard, transition, and soft metals (Buffle, 1988; Sparks, 2003) as will be discussed later (Table 8.1). Furthermore, in view of

TABLE 8.1 Hard and Soft Acids and Bases

Lewis Acids	Lewis Bases

the stability constants of these biomolecular ligands with metals (NIST, 1997), a substantial fraction of the soluble metal ions in the soil solution may be complexed with a series of biomolecules commonly present in microbial metabolites and root exudates. The concentrations of metals such as Cu, Mn, Zn, and Co in the rhizosphere vary with seasons and are related to the presence of complexing biomolecules (Nielson, 1976; Linehan et al., 1989). The pH of the rhizosphere soil is generally lower than that of the corresponding bulk soil. The cadmium availability index (CAI) values in the rhizosphere are higher, indicating that more Cd is complexed with biomolecules at the soil-root interface (Krishnamurti et al., 1996). The plant root and prolific microbial activity should result in increased amounts of biomolecules. A larger fraction of the metal contaminant will thus be in a complexed and usually soluble form in the soil-root interface than in the bulk soil.

The research of metal speciation of the soil solution has been encouraged by the free metal ion hypothesis in environmental toxicology (Lund, 1990). This states that the toxicity or bioavailability of a metal is related to the activity of the free aquo ion. This hypothesis is gaining popularity in studies of soil–plant relations (Parker et al., 1995). However, some evidence is now emerging that free metal ion hypothesis may not be valid in all situations (Tessier and Turner, 1995). Plant uptake of metals varies with the kind of chelators present in solution at the same free metal activity. Furthermore, given the same chelate, total metal concentration in solution affects metal uptake by plants. Either kinetic limitations to dissociation of the complex or uptake of the intact complex could explain these observations (Laurie et al., 1991).

8.3 Sorption/Desorption Processes of Metal(loid)s in Soils

The soil components responsible for trace element sorption include soil organic matter, phyllosilicates, carbonates, microorganisms, and variable charge minerals (constituents such as Fe, Al, Mn, and Ti oxides, short-range ordered aluminosilicates as well as phyllosilicates coated by OH-Al or OH-Fe species) whose charge varies with the pH of the soil solution (Parfitt, 1980; Jackson, 1998; Huang and Germida, 2002; Sparks, 2003; Violante et al., 2008). Soil components differ greatly in their sorption capacities, their cation and anion exchange capacities, and the binding energies of their sorption sites. However, in soil environments, organic matter, phyllosilicates, OH-Fe and OH-Al species, and short-range ordered metal oxides are constantly in close association with each other, forming organomineral complexes, which have different shape, size, charge and reactivity toward nutrients and pollutants, including metals and metalloids (Violante and Gianfreda, 2000; Chapter 2). Organomineral complexes have peculiar chemical and physicochemical properties and reactivity toward nutrients and metals and metalloids, which differ from those of each soil component present in these aggregates (Violante and Gianfreda, 2000). In some soils, particularly those high in humic substances, the clay minerals may be coated with humic substances. It has been estimated that from 52% to 98% of all carbon in soils occurs as clay–soil organic matter complexes (Greedland, 1965; Sparks, 2003; Chapter 2 of Handbook of Soil Sciences: Properties and Processes). It is likely that most of the remaining organic C is linked to metal oxides (Schnitzer and Kodama, 1977).

The sorption/desorption processes of metal(loid)s in cationic form differs greatly from those of elements in anionic form. An excellent review on modeling adsorption of metals and metalloids by soil components has been published by Goldberg and Criscenti (2008).

8.3.1 Sorption of Heavy Metals in Cationic Form

Heavy metals cations show typical ion exchange behavior on layer silicate clays with permanent charge, demonstrating similar affinity for exchange sites on the clays as do alkaline earth metals having the same charge and similar ionic radious. Trace metals are probably not dominantly sorbed on 001 faces of phyllosilicates because they are always vastly outnumbered by other cations with which they compete (Jackson, 1998). Surface bonding is electrostatic, dependent only on the charge and hydration properties of the cation. The high selectivity of some phyllosilicates for trace quantities of heavy metals (relative to metals as Ca or Mg) may indicate the presence of a few sites on the clays capable of chemisorbing these metals. These sites may be –SiOH or –AlOH groups on the edges of the phyllosilicates (McBride, 1991). However, clay minerals have also an important role as carriers of associated oxides and humic substances forming organo-mineral complexes.

Substantial evidence has demonstrated that organic matter and metal oxides are much more effective scavengers of trace elements in cationic form, than even the most efficient sorbent among phyllosilicates, indicating that specific sorption and other complexation processes are the dominant binding mechanisms (Jackson, 1998; Huang and Germida, 2002; Huang, 2008; Violante et al., 2008). Two general surface complexes exist and are described by the configuration geometry of the adsorbate at the adsorbent surface. These include inner- and outer-sphere surface complexes and are defined by the presence, or absence, of the hydration sphere of the adsorbate molecule upon interaction. When at least one water molecule of the hydration sphere is retained upon adsorption the surface complex is referred to as outer-sphere. When the ion is bound directly to the adsorbent without the presence of the hydration sphere, an inner-sphere complex is formed (Sposito, 1986, 2004; Sparks, 2003; Borda and Sparks, 2008).

Besides some noncrystalline minerals that have very high specific surface charge density with highly reactive sites, organic matter appears to have the greatest capacity for sorption of trace elements in cationic form.

Soil organic matter consists of a spectrum of materials, ranging from compounds that mineralize very easily during the first stage of decomposition to more resistant materials that accumulate as microbial by-products as well as humified materials

formed by enzymatic and mineral catalyses. Soil organic compounds are of two major types: (1) well-defined biochemical substances produced by microorganisms and plants, such as *simple*, LMMOAs, siderophores, hydroxamate, sugar acids, phenols and phenolic acids, and *complex*, polymeric phenols, lipids, polysaccharides, nucleic acids and proteins; and (2) a series of acidic, yellow- to black-colored substances formed by enzymatic and mineral catalysis reactions, which are referred to as humic and fulvic acids as well as humin materials that are regarded as humic substances (Stevenson, 1976; Sparks, 2003; Huang and Hardie, 2009). Molar mass of organic compounds range from >3000 Da for humic acids, 1000–3000 Da for fulvic acids, and <1000 Da for low-molar-mass organic acids.

In the rhizosphere, root exudates comprise both high and low-molar-mass substances released by the roots and microorganisms. The most important high-molecular-mass compounds are mucilage, polysaccharides, and ectoenzymes, whereas the main constituents of the low-molecular-mass compounds are carbohydrates, organic acids, amino acids, peptides, and phenolics.

Humic substances contain a large number of complexing sites and thus behave as a natural "multiligand" complexing system (Buffle, 1988). The high degree of selectivity of soil organic matter for most of trace metals in cationic form indicates that they form inner-sphere complexes with the functional groups, often forming internal five- or six-member ring on structures (Senesi, 1992; Senesi and Loffredo, 1998; Huang and Germida, 2002; Sparks, 2003). As summarized by Senesi and Loffredo (2008) the most common stoichiometries assessed are humic acid:metal = 1:1 and 2:1, often involving the formation of metal chelates. Aromatic carboxyls and phenolic groups play a prominent role in the 1:1 binding of metal ions by soil humic and fulvic acid, by forming chelates that involve either two COOH groups in a phtalate-type site or one phenolic group and one -COOH group in a salicylate-type site. Nonaromatic carboxyl and hydroxyl sites, including pyruvate-type and glycolate-type sites and carbohydrate moieties, may also be involved in metal ion binding by soil humic and fulvic acid. Other possible combinations involve two phenolic OH, quinone, NH₂, and sulfydryl groups, and conjugated ketonic structures (Stevenson, 1976; Chen and Stevenson, 1986; Senesi and Loffredo, 2005, 2008). Metal ions may also coordinate with ligands belonging to two (or more) humic substances molecules, forming 2:1 complexes and/or chelates, and eventually producing chain structures that may result in the aggregation and precipitation as the chain grows at high metal to humic substances ratios (Stevenson, 1976; Senesi and Loffredo, 2008). The total binding capacity of humic acids for metal ions is about 200-600 mmol kg⁻¹. About 33% of this total is due to retention on cation-complexing sites.

Complexation reactions of metals with ligands in the soil solution are significant in determining the chemical behavior and toxicity of metals in the rhizosphere, where LMMOAs are continuously released as root exudates and microbial metabolites. The hard and soft acid-base rules are useful in predicting the association between cations and ligands. According to the Pearson terminology, Lewis acids and bases can be classified

on a scale of "hard" to "soft." Soft bases (ligands) are large molecules that are easily polarized: they readily donate electrons to form covalent bonds. They selectively bond with soft acids, typically metal ions of relatively large radius and low charge. Hard bases tend to be small molecules that are not easily polarized and form less covalent and more ionic bonds, preferentially with hard acids, typically metal ions of small radius and high charge. Therefore, soft acids bond preferentially with soft bases and hard acids bond preferentially with hard bases. The classification of Lewis acids and bases is listed in Table 8.1.

For soft metals (Cu^{2+} , Cd^{2+} , Hg^{2+}), the donor atom affinity follows the order: O < N < S, whereas the reverse order is observed for hard metals. In general, the competitive reactions for a given ligand essentially involve hard cations and transition metals for O sites and transition and soft metals for O and O sites, with competition between hard and soft metals being weak (Sparks, 2003).

Complexation reactions have the following effects: (1) metal ions are prevented from being precipitated; (2) complexing agents can act as carriers for trace elements in soil solution; and (3) their toxicity is often reduced by complexation. Stability constant (*K*) of trace metal complexes with humic acids increases with increasing pH and decreasing ionic strength. A number of reviews have been published on the chemistry of complexation of metals with organics and the spectroscopic techniques for studying metal–humic complexes in soil, to which the reader can refer for details (Stevenson and Fitch, 1986; Senesi, 1990; Senesi and Loffredo, 2008).

Unlike the phyllosilicates, the ability of variable charge minerals (crystalline and short range ordered Fe-, Al-, Mn-oxides, allophanes, imogolite) to retain trace metals is pH-dependent. On these materials, a hydroxylated or hydrated surface, positive or negative charge is developed by adsorption or desorption of H+ or OH- ions (Figure 8.1A). The pH at which the net variable charge on the surfaces of these components is zero is called the point of zero charge (PZC). The reported PZC of Fe-oxides ranges from pH 7.0 to 9.5, whereas that of Al-oxides ranges from pH 8.0 to 9.7. (Kwong and Huang, 1979; Hsu, 1989; Cornell and Schwertmann, 1996; Huang et al., 2002; Violante et al., 2005). Crystalline metal oxides usually have specific surface of 15–70 m² g⁻¹, whereas short-range ordered precipitates may have specific surface even greater than 200-300 m² g⁻¹. Organic components (fulvic and humic acids) as well as other organic and inorganic ligands have a very important role in the formation of short-range ordered materials. They can interact with Al and Fe perturbing their transformations, retarding or inhibiting the crystallization of Al and Fe precipitates (Huang and Violante, 1986; Violante et al., 2002, 2005). Crystalline and short-range ordered variable charge minerals selectively sorb polyvalent cations even when the net charge of their surfaces are positive (solution pH values lower than the PZC of the sorbent) (Figure 8.1).

Most transition cations (Pb, Cu, Cr, Ni, Co, Zn, Al, Fe, Mn) are often sorbed more strongly than alkaline earth cations. Spectroscopic techniques such as electron spin resonance (ESR) and extended x-ray absorption fine structure spectroscopy (EXAFS) have been used for the identification of metal

FIGURE 8.1 Coordination phenomena at oxide-water interface: (A) acid-base reactions of surface hydroxyls; (B) coordination of deprotonated groups with dissolved metal ions; (C) exchange of surface hydroxyls by dissolved oxyanions; (D) coordination of dissolved metal ion with both deprotonated surface hydroxyls and dissolved ligands; (E) coordination of dissolved multidentate ligand with both metal ion on the surface (X) and the dissolved metal ion (M). (Modified from Parfitt, R.L. 1980. Chemical properties of variable charge soils, p. 167–194. *In* B.K. Theng (ed.) Soils with variable charge. New Zealand Society of Soil Science, Palmerston North, New Zealand.)

complexes at the surfaces of Al, Fe, or Mn oxides, silicate clays, and soil organic matter (Sparks, 1999). The mechanism of metal ion association with hydrous oxide surfaces involves an ion exchange process in which the sorbed cations replace bound protons (Figure 8.1B). Usually, specifically sorbed cations raise the value of PZC of variable charge minerals. pH affects sorption of trace elements, either by changing the number of sites available for sorption (sorption increases by increasing pH) or by changing the concentration of cation species (Me²⁺, MeOH+, Me(OH)₂).

Sorption of metal cations is pH-dependent (Figure 8.2). Sorption, which increases from 0% to 100% of the amount added over a narrow region of 1–2 pH units, is termed as "sorption edge." The pH at which 50% of the total sorption has occurred is called pH $_{50}$. The lower the pH $_{50}$ of a trace element for a sorbent the stronger is the element–surface complex (Kinniburgh and Jackson, 1976, 1981). The pH $_{50}$ position of the sorption edge for a given trace element is related to the hydrolysis or acid–base characteristics. In addition to pH, sorption of metals is dependent on sorptive concentration, surface coverage, and the type of the sorbents (Sparks, 2003; Violante et al., 2003, 2008).

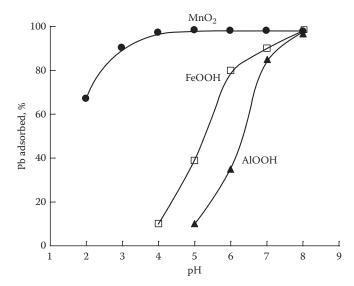

FIGURE 8.2 Effects of pH on the adsorption of Pb by Mn, Fe, and Al oxyhydroxides. (Modified from Gadde, R.R. and H.A. Laitinen. 1974. Studies of heavy metals adsorption by hydrous iron and manganese oxides. Anal. Chem. 46:2022–2026.)

Experiments with various synthetic Fe, Al, and Mn oxides showed that the affinity of trace elements for Mn oxide was usually much greater than that for Fe or Al oxides (Figure 8.2). However, the nature, crystallinity, size of the crystals, surface charge of metal oxides and mixed metal oxides (e.g., Fe–Al oxides) also play an important role in the sorption selectivity of trace elements in cationic form (Kinniburgh and Jackson, 1976, 1981; Pickering, 1979; McKenzie, 1980; McBride, 1982; Sparks, 2003; Violante et al., 2003, 2008).

Pickering (1979) recorded the following affinity series for freshly precipitated Fe, Al, and Mn oxides:

Fe-oxide: Pb > Cu > Zn > Ni > Cd > Co > Sr > Mg

Al-oxide: Cu > Pb > Zn > Ni > Co > Cd > Mg > Sr

Mn-oxide: Cu > Pb > Mn > Zn > Ni

Evidence on the sorption of trace elements on microorganisms has been reported. Free-living bacteria and their extracellular macromolecular products (e.g., fibrils) can accumulate trace elements and may have mineral coatings with bound metals on their surfaces (Beveridge, 1989a, 1989b; Jackson and Leppard, 2002, and references there in). All microorganisms contain biopolymers such as proteins, nucleic acids, and polysaccharides that provide reactive sites for binding metal ions. The cell surfaces of all bacteria are largely negatively charged containing different types of negatively charged functional groups, such as carboxyl, hydroxyl, and phosphoryl that can adsorb metal cations, and retain them by mineral nucleation. *Bacillus subtilis*, for example, has an isoelectric point at pH 2.4, and an average surface charge excess of 1.6 µmol mg⁻¹ dry biomass over the pH range of 2.4-9. Accordingly, bacterial cell walls have a strong affinity for metal cations. Yee and Fein (2001) demonstrated that Cd sorption onto various Gram-positive and Gram-negative bacterial species was pH-dependent and the sorption edge behavior was similar to those of trace elements onto oxides. Even dead bacterial cells are also highly efficient in accumulating both soluble and particulate forms of metals. Bacteria therefore play an important role in the speciation, fate and transport of metals, metalloids, and radionuclides in soil and associated environments.

Biosorption comprises a variety of processes including ion exchange, chelation, adsorption, and diffusion through cell walls and membranes, all of which are dependent on the species used, the biomass origin, and solution chemistry (Gavrilescu, 2004). Lopez et al. (2000) reported the following affinity order for the surfaces of microorganisms: Ni \gg Hg > U \gg As > Cu > Cd > Co > Cr > Pb. Biosorption is a fast and reversible process for removing toxic metal ions from solution. Many environmental factors influence the chemical reactivity of the binding sites on bacterial cell surfaces and the subsequent biosorption of metals. These factors include pH, ionic strength, temperature, and the presence of other metals and organic compounds. The binding of metals by bacteria is also affected by nutrient and oxygen levels.

The ability of bacteria to accumulate toxic metals also varies with cell age. Huang et al. (2008) reported that 1-day-old cells of *Thiothrix* strain A1 accumulated considerably less Ni or Zn than its 2- to 5-day-old counterparts. However, the biosorptive capacity of dead cells may be greater, equivalent to, or less than that of living cells. For example, biosorption of Cr by the dead cells of *B. circulans* and *B. megaterium* was higher than by living cells (Srinath et al., 2002).

8.3.2 Sorption of Metal(loid)s in Anionic Form

Trace elements that exist in anionic form are sorbed primarily by chemisorption at reactive sites of metal oxides and allophanes (Figure 8.1C) and at the edges of phyllosilicates (Cornell and Schwertmann, 1996; Smith et al., 1998; Kampf et al., 2000; Violante et al., 2002). Usually, they are not sorbed on soil organic matter, but certain elements (e.g., borate, arsenate, arsenite) are found to be bound to humic acids (Thanabalasingan and Pickering, 1986; McBride, 2000). Arsenate and arsenite have maximum adsorption on humic acids at pH 5.5 and 8.0, respectively (Thanabalasingan and Pickering, 1986). Arsenate adsorbs onto solid-phase humic acids more extensively than arsenite, with amine (NH₂) groups suspected as the primary functional group responsible for arsenic retention. Some anions may bond indirectly to organic groups through a bridging hydrolytic species of Al, Fe, and Mn. Carbonates are also important sorbing surfaces (Goldberg and Glaubig, 1988a, 1988b).

Sorption of anions onto variable charge minerals and soils varies with pH. With increasing pH, within a certain range, sorption decreases (due to a decrease of positive charge of minerals) or else increases to a maximum close to the pK_a for anions of monoprotic conjugate acids and then decreases. Arsenite and selenite may be sorbed more easily at high pH values because they form weak acids at low pH values and consequently may be

dissociated only in alkaline environments (Violante et al., 2008). Anions may be specifically or nonspecifically sorbed, forming inner-sphere or outer-sphere complexes. Ligands that are specifically sorbed replace OH⁻ or OH₂ groups from the surfaces of variable charge minerals, which involve direct coordination to the surface metal atom (Figure 8.1C). Specifically sorbed anions usually lower the PZC of metal oxides; thus, the PZC of a particular oxide may give rise to different values depending on the kind and extent of foreign ion sorption.

Trace elements, which form inner-sphere complexes, are arsenate, arsenite, molybdate, and selenite, which may form different surface complexes on inorganic soil components: monodentate, bidentate-binuclear, and bidentate-mononuclear complex in different proportions depending on pH and surface coverage (Hsia et al., 1994; Sun and Doner, 1996; Fendorf et al., 1997; Manning et al., 1998; O'Reilly et al., 2001; Ona-Nguema et al., 2005). Many studies have demonstrated that arsenite is sorbed on Al-oxides, phyllosilicates, and calcite in a lesser extent than arsenate, whereas the opposite is true for iron oxides (Violante et al., 2008).

Soil selenium content is significantly correlated with total carbonate, free-Fe-oxide, and extractable Al and Fe and clay content. Selenite sorption onto soil components and soils is much greater than selenate (Goldberg and Glaubig, 1988a). Using EXAFS measurements, Hayes et al. (1987) ascertained that selenate formed a weakly bonded, outer-sphere complex and selenite formed a strongly bonded, inner sphere complex when sorbed on goethite. However, Manceau and Charlet (1994) found that selenate may also form inner-sphere complexes onto goethite analogous to sulfate.

The sorption mechanism of chromate is unclear. Zachara et al. (1989) suggested that chromate forms an outer-sphere complex on the surfaces of Fe and Al oxides. However, spectroscopic studies have shown that chromate forms inner-sphere complexes (both bidentate and monodentate) on goethite (Fendorf et al., 1997). Furthermore, in contrast to surface complexation modeling results, competitive ion displacement studies have shown that Cr(VI) is retained much more strongly than anions such as Cl^- or $SO_4^{\ 2^-}$, and that its retention strength approaches that of phosphate. There are various sorption mechanisms involving both physical and chemical processes that could occur for heavy metals and metalloids at soil mineral surfaces, as summarized by Sparks (2003, see Table 5.1).

Trace elements in anionic form may be easily sorbed by "anionic clays" (layered double hydroxides [LDHs]), which are present in soils. For example, "green rusts" are green-blue Fe(II) Fe(III) hydroxides, which are formed by a number of abiotic and biotic processes under circumneutral to alkaline conditions in suboxic environments and are postulated to be intermediate phases in the formation of iro(oxyhydro)oxides such as goethite, lepidocrocite, and magnetite (Cornell and Schwertmann, 1996; Violante et al., 2002). They may be important for trace metal mobility because of their high reactive surface area. Many studies have been carried out on the possible use of LDHs, which are also easily synthesized, as powerful filters for removing

xenobiotics in anionic forms from polluted waters (Goh et al., 2008; Violante et al., 2009b).

8.3.3 Kinetics of Sorption

Sorption/desorption of trace elements in soils can occur over wide timescales. The mineralogical, chemical, and physicochemical properties of inorganic and organic sorbents and microorganisms of a soil affect the sorption/desorption processes. In particular, trace element sorption kinetics on phyllosilicates, Al, Fe, or Mn oxides and humic substances depend mainly on the nature of the surfaces of the sorbents and trace element being studied. Sorption reactions are often more rapid on kaolinite and smectite than on vermiculitic and micaceous minerals. In fact, kaolinite has readily available planar external sites and smectites have predominantly internal sites that are quite available for retention of sorbates. Thus, sorption reactions on these soil constituents are often quite rapid, even occurring on timescales of seconds and milliseconds (Sparks, 1989, 2003). On the other hand, vermiculite and micas have multiple sites for retention of ions, including planar, edge, and interlayer sites, with some of the latter sites being partially to totally collapsed. Therefore, sorption and desorption reactions on these sites can be slow, tortuous, and mass transfercontrolled. Often, an apparent equilibrium may not be attained even after several days or weeks (Borda and Sparks, 2008).

The use of pressure-jump relaxation and other relaxation techniques have shad light in the study of sorption measurements on soil components (Sparks and Zhang, 1991; Sparks, 1995). An especially attractive approach for ascertaining sorption mechanisms on soils would be to combine relaxation approaches with in situ surface spectroscopic techniques. However, there are a few examples in the literature of studies where sorption reactions on soil components have been hypothesized via kinetic experiments and verified in separate spectroscopic investigations (Fuller et al., 1993; Waychunas et al., 1993; Fendorf et al., 1997; Grossl et al., 1997; Scheidegger et al., 1997; Borda and Sparks, 2008).

Sorption processes of metals and metalloids are initially rapid, with a large amount of the total sorption occurring within a few hours and the remaining sorption often occurring over long periods of time. The rapid step, which occurs over milliseconds to hours, can be ascribed to chemical reaction and film diffusion processes (Sparks, 2003). During this rapid reaction process, a large portion of the sorption may occur. A number of studies have shown that sorption/desorption of metals, oxyanions, radionuclides, and organic chemicals on soils can be slow, and may demonstrate a residence time effect (contact time between trace element and sorbent), as will be discussed later. The mechanisms for these lower reaction rates are not well understood, but have been ascribed to diffusion into micropores of inorganic minerals such as some metal oxides and into humic substances, retention on sites of varying reactivity, and to surface nucleation/precipitation (Borda and Sparks, 2008, and references therein). In some cases, the magnitude of sorption can greatly increase with longer reaction times. For example, Bruemmer et al. (1988) studied Ni^{2+} , Cd^{2+} , and Zn^{2+} sorption on goethite, a porous Fe oxide that has defect structures in which metals can be incorporated to satisfy charge imbalances. It was found at pH 6 that as reaction time increased from 2h to 42 days, adsorbed Ni^{2+} increased from 12% to 70% of total sorption, and total Cd^{2+} and Zn^{2+} sorption over the same time increased by 21% and 33%, respectively.

An excellent review on kinetics and mechanisms of sorption–desorption in soils includes those of Sparks (1989) and Borda and Sparks (2008).

8.3.4 Surface Precipitation and Reduction-Oxidation Reactions

8.3.4.1 Surface Precipitation

Sorbed trace element species may range from simple cations to complex polynuclear hydroxides formed by hydrolysis and condensation in solution or by nucleation on the mineral surfaces (McBride, 1991; Jackson, 1998). As the amount of metal cation or anion sorbed on a surface (surface coverage or loading, which is affected by the pH at which sorption occurs) increases, sorption can proceed from mononuclear adsorption to surface precipitation (a three-dimensional phase). There is often a continuum between surface complexation (adsorption) and surface precipitation. At low surface coverages, surface complexation (e.g., outer- and inner-sphere adsorption) tends to dominate. As surface loadings increase, nucleation occurs and results in the formation of distinct entities or aggregates on the surface. As surface loadings increase further, surface precipitation becomes the dominant mechanism (Sparks, 2003, 2005). When the precipitate consists of chemical species derived from both the aqueous solution and dissolution of the mineral, it is referred to as a coprecipitate. The composition of the coprecipitate varies between that of the original solid and a pure precipitate of the sorbing metal.

In the last decade, extensive research has been carried out on the heterogeneous precipitation of trace elements on the surfaces of minerals, using modern spectroscopy techniques such as synchrotron-based x-ray absorption spectroscopy (Sparks, 2003). Laboratory studies of metal partitioning identified the incorporation of Cr, Ni, Co, Cu, and Zn into a neoformed surface precipitates. Depending on the reaction conditions, time, and adsorbent phase present, either a metal hydroxide, a mixed LDH, or a phyllosilicate form at the mineral surface. Many studies have shown that sorption of metals, such as Ni, on an array of phyllosilicates and Al oxide could result in formation of mixed metal-Al hydroxide surface precipitates, which appear to be coprecipitates. These neoformed phase shares structural features common to the hydrotalcite group of minerals and the LDHs, also known as anionic clays. The crystal structure of LDHs consists of positively charged octahedral hydroxide layers, which are neutralized by the interlayer anions and water molecules. These minerals have the general formula $[M_{1-x}^{2+}M_x^{3+}(OH)_6]^{x+}[(A^{n-})_{x/n} mH_2O]^{x-}$ with x taking values between 0.20 and 0.33 (Miyata, 1975; Cavani et al., 1991) where M2+ and M3+ are divalent (Ca, Mg, Co, Fe, Cu, Ni, Mn) and trivalent metal cations (Al, Fe, Cr), respectively, and A is an interlayer anion (Cl, NO_3 , ClO_4 , CO_3 , SO_4 and so on) of charge -n. The anions in the interlayer spaces can be replaced with any inorganic and organic anion by simple ion exchange methods. These minerals can be considered complementary to the cationic clays whose negative charge of the aluminosilicate layers are counterbalanced by cations.

The ionic radius of the sorbing metal and sorbent ions must be similar for coprecipitates to form. Mixed Co–Al, Ni–Al, and Zn–Al hydroxide surface precipitates form on aluminum-bearing metal oxides and phyllosilicates, having Co²⁺, Zn²⁺, and Ni²⁺ similar radii to Al³⁺, enhancing substitution in the mineral structure and formation of a coprecipitate. However, surface precipitates have not been observed with Pb²⁺, as Pb²⁺ is too large (0.12 nm) to substitute for Al³⁺ in mineral structures (Sparks, 2003, 2005).

Surface precipitates can start to form on timescale of minutes and then growing in amount for hours or days. The initial precipitates are stabilized upon aging. This stabilization (residence time effect) has been attributed to the transformation of a mixed LDH phase into a more stable phyllosilicate phase. In other words, the metal sorption on soil minerals can often results in a continuum of processes from adsorption to precipitation to solid phase transformation. As a consequence, heavy metals become less mobile and bioavailable with time.

The effect of residence time on the rearrangement of trace elements in anionic form from desorbable into resistant and undesorbable forms has been studied and evidenced (Arai and Sparks, 2002; Pigna et al., 2006).

The effects of humic and fulvic acid on Ni sequestration mechanism in kaolinite and boehmite have been recently investigated (Nachtegaal and Sparks, 2003; Strathmann and Mynemi, 2005). Spectroscopic evidence indicates that the formation of Ni LDH phases can be suppressed by the amount of humic acid coatings on kaolinite surface via direct Ni sorption on humic acid functional groups and/or by the formation of Ni-fulvic acid-boehmite ternary species. In particular, Nachtegaal and Sparks (2003) showed that in the presence of 1 wt% of humic acid a Ni-Al LDH precipitate was formed at the kaolinite surface, but in the presence of 5 wt% of humic acid its formation slowed significantly and the precipitate formed was similar to Ni(OH)2. However, the Ni(OH), precipitate was not resistant to proton dissolution while the Ni-Al LDH was. These results augment the findings that the incorporation of first row transition metals into stable surface precipitates is an important sequestration pathway for toxic metals in the environment, despite the presence of ubiquitous coating materials such as humic or fulvic acids.

Yamaguchi et al. (2002) studied the influence of surface area of gibbsite on Ni sorption in the ternary Ni-gibbsite-citrate system over time. At low surface area and corresponding high surface loading, a Ni–Al LDH precipitate formed. At high surface area and lower surface loading, formation of an inner-sphere surface complex prevailed and a small amount of Ni–Al LDH formed only after an extended ageing period. Citrate reduced the amount of Ni sorbed but the effect was more pronounced

for the gibbsite with a low surface area than for that with a large surface area. Furthermore, citrate prevented the formation of an LDH phase.

8.3.4.2 Redox Reactions

Changes in the oxidation state of trace metals can occur depending on the redox condition of the environment. Redox reactions are then important in influencing the chemical speciation of a number of metals and metalloids (Sparks, 1995). Trace elements that are directly influenced by electron transfer include Cr [Cr(III), Cr(VI)], Se [Se(IV), Se(VI)], As [As(III), As(V)], as well as Co, Pb, Ni, and Cu.

Clays and oxides often demonstrate the ability to catalyze electron transfer reactions (Huang and Hardie, 2009). Iron and manganese oxides and layer silicates with structural Fe(III) are the most active in this regard. Redox reactions also control the transformation and reactivity of Fe- and Mn-oxides in soils, which are the major sinks for heavy metals and metalloids. Many of the transition metal cations (Ni2+, Zn2+, Pb2+, and Cd²⁺), which are not always directly impacted by electron transfer, are moderately mobile in an oxidized environment, but they present a relative mobility in a reduced environment very low to immobile. In a reducing environment, sulfur is found in the reduced form (S2-) and metal concentrations in solution are controlled by the solubilities of sulfide minerals (e.g., NiS, ZnS, CdS, and PbS), which are much more stable than the minerals found in oxidized systems (James and Bartlett, 2000; Sparks, 2003).

Redox-reactive metals often do have different degrees of toxicity depending on the specific metal oxidation state. Chromium is one such metal ion that persists in the environment as either Cr(III) and Cr(VI). Chromate is toxic to plants, animals, and humans and is a suspected carcinogen, whereas Cr(III) is not toxic to plants and is necessary in animal nutrition, so that reactions that reduce Cr(VI) to Cr(III) are of great importance. Furthermore, Cr(VI) is mobile in soils and readily available. Organic material, sulfides, and ferrous species appear to be the dominant reductants. Very stable Cr(III)—organic complexes form when Cr(VI) is reduced by soil organic matter (Fendorf, 1995).

The efficiency of the Mn oxides as "electron pump" for a wide range of redox reactions is unique among common soil minerals. Manganese oxides have been proven to be the only naturally occurring oxidant of Cr(III), so that they can enhance the mobility and toxicity of Cr, as Cr(VI) and Pu(VI), which can result from oxidation of Pu(III) by Mn-oxides, is very toxic and mobile in soils and water. Manganese oxides and hydroxides may also catalyze the oxidation of other trace metals such as Co²⁺, Co³⁺, Cu²⁺, Ni²⁺, Ni³⁺, and Pb²⁺ by disproportionation to Mn²⁺ and MnO₂. The disproportionation results in vacancies in the Mn oxide structure. Since the Mn²⁺ and Mn³⁺ in the oxides have similar physical sizes as Co²⁺, Co³⁺, Cu²⁺, Ni²⁺, Ni³⁺, and Pb²⁺ these metals can occupy the vacancies in the Mn oxide and become part of the structure (Huang and Germida, 2002; Sparks, 2003; Huang and Hardie, 2009).

Manganese oxides can also oxidize As(III) to As(V). This reaction has important implications for the transport, fate, and toxicity of As in natural environments, because As(III) is more toxic to human and more mobile than As(V). The ability of Mn oxides to oxidize As(III) to As(V) varies with their crystallinity and specific surface, but the kinetic of reaction is generally very fast. Under controlled laboratory conditions, the apparent half-lives for oxidation of As(III) are less than 1h (Oscarson et al., 1981, 1983). In contrast, whereas Sun and Doner (1996) demonstrated that oxidation of sorbed As(III) to As(V) on Fe(III) oxides may occur to a limited (about 20%) extent.

Reduction of some trace elements is promoted by "green rusts." These components are able to reduce Se(VI), Cr(VI), and U(VI), but cannot reduce As(V) to As(III) (Loyaux-Lawniczak et al., 2000; Refait et al., 2000). Transition metal exchange cations on clays can also promote oxidation–reduction reactions. For example, adsorbed Cu²⁺ on smectite can oxidize benzene and benzidine by a single electron reaction, forming radical cations that appear to be stabilized at the surface (McBride, 1989).

Important microbiological processes controlling the oxidation and reduction of metals and metalloids in natural environments have been reviewed by Ehrlich (1997, 2002a, 2002b), Frankenberger (2002), and Gadd (2008).

The changes in soil redox potential and biological activity in the rhizosphere and their effects on the phytoavailability of metal(loid)s will be addressed later.

8.3.5 Competition in Adsorption of Metal(loid)s

Competition in sorption between two or more metals or metalloids is of great importance for understanding their relative affinity for a given sorbent. Lack of competition of different cations may be due to low surface coverage and only partially to the different binding sites having high selectivity for specific metals and metalloids (Kretzschmar and Voegelin, 2001).

Competition between different trace elements is easily ascertained at high surface loading of the sorbents with sorbed cations. Violante et al. (2008) have reviewed the competition of selected trace elements in binary systems onto inorganic and organic soil components and soils. Simine et al. (1998) found that lead competes with Cd for attachment to bacterial surface sites when a solution containing both metals was added.

Few studies have been carried out on the competition of three or more trace elements onto soil components or soils. Recently, the competitive sorption of Cu, Cr(III), and Pb in binary and ternary systems on a ferrihydrite was studied (Zu et al. 2010). Figure 8.3 shows the amounts of each metal sorbed when added alone or in competition with another heavy metal in the systems Cr:Cu, Cu:Pb, and Pb:Cr at pH 4.5 and at cation molar ratio of 1. More Pb (80%) than Cr (67%) or Cu (25%) was sorbed when each cations was added alone (100 mmol added per kg). In binary systems, Pb reduced Cr and Cu sorption by 26% and 39%, Cr reduced Cu and Pb sorption by 35% and 11%, and, finally Cu inhibited Cr and Pb sorption by 11% and 1%, respectively (Figure 8.3). The stronger

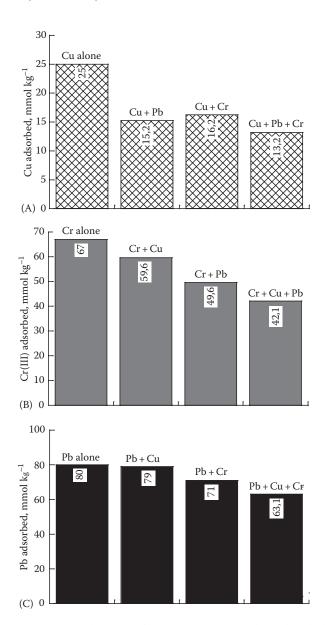

FIGURE 8.3 Total amount of (A) Cu, (B) Cr(III), and (C) Pb sorbed onto ferrihydrite added alone or in binary and ternary systems at equal molar ratio. (Modified from Zhu, J., M. Pigna, V. Cozzolino, A.G. Caporale, and A. Violante. 2010. Competitive sorption of copper(II), chromium(III) and lead(II) on ferrihydrite and two organomineral complexes. Geoderma 159:409–416.).

capacity of Pb in preventing the sorption of the other two cations appeared evident when the three cations were added simultaneously at equimolar amounts ($100\,\mathrm{mmol\ kg^{-1}}$) to the ferrihydrite suspension. The proportion of the cations sorbed on the Fe oxide was 53.3% of Pb, 35.6% of Cr, and 11.1% of Cu. This substantiates the finding that the affinity of the three cations followed the sequence Pb > Cr \gg Cu. Anyway, by adding the three cations at an initial Pb:Cr:Cu molar ratio of 2:1:1 (not shown), the sorbed cations were for 73.0% Pb, 20.8% Cr, and 6.2% Cu. These findings indicate that even in the presence of high concentrations of Pb, some sites were apparently specific for Cr and Cu.

Elliott et al. (1986) studied the competitive sorption of Cd, Cu, Pb, and Zn onto four soils with different chemical properties. For two mineral soils, sorption under acidic conditions (pH 5.0) followed the sequence Pb > Cu > Zn > Cd, which corresponds to the order of increasing pK for the first hydrolysis product. For two soils with high organic matter content, the order was Pb > Cu > Cd > Zn.

Capasso et al. (2004) demonstrated that the presence of both Zn and Cu did not affect the capacity of Cr(III) to be sorbed onto an humic-like material (polymerin). In contrast, at an equilibrium concentration of 4 meq L^{-1} , the concomitant presence of Zn and Cr(III) decreased Cu sorption by about 50%, with Cr(III) being much more effective than Zn in preventing Cu sorption, whereas Cu and Cr(III) decreased Zn sorption by 79%.

Competition in sorption of trace elements in anionic form has received some attention (Violante et al., 2008). Manning and Goldberg (1996) studied the effects of pH and competing molybdate and arsenate ions onto goethite and gibbsite. Molybdate at 50% surface coverage decreased the sorption of arsenate only at pH < 6.0, whereas arsenate reduced molybdate sorption within a wider pH range (2–9 for goethite and 2–8 for gibbsite).

Goldberg and Glaubig (1988a) studied the competitive effect of selenite on arsenate sorption on a calcareous montmorillonite soil. Arsenate sorption was unaffected by the presence of selenite over a wide range of pH (1–13). These results indicate that these anions sorb on separate sites or, more probably, sorption sites were not limiting at the low concentrations used. However, Zhu et al. (2011) found that the influence of selenate (at about 80% surface coverage for arsenic) in preventing arsenite and arsenate sorption onto ferrihydrite was negligible when the two ligands were added in equimolar amounts at pH 6.0, whereas selenite reduced arsenite and arsenate sorption by 22% and 17%, respectively (Figure 8.4A and B). The efficiency of selenite and selenate increased at lower pH values and at a greater Se(III or V)/As(III or V) molar ratio.

Wu et al. (2001) found that molybdate sorption was insignificantly affected in the presence of equimolar amounts of selenate; however, selenate sorption was significantly reduced in the presence of molybdate at pH < 7.0, where a 30% decrease in sorption was noticed.

8.3.6 Influence of Inorganic and Organic Ligands on the Sorption of Metal(loid)s

Many factors such as pH, surface properties of the sorbents, the number of sites available for sorption, and the nature and charge of species of metals and metalloids in solution influence their sorption onto soil inorganic components (phyllosilicates and variable charge minerals) in the presence of inorganic and biological ligands (Kinniburgh and Jackson 1976, 1981; McBride, 1989; Goldberg et al., 1996; Jackson, 1998; Violante et al., 2003, 2008).

Inorganic and organic ligands (e.g., organic acids), which form strong complexes with trace element cations usually prevent or reverse their association with negatively charged sorbents, as 2:1 expandable phyllosilicates, by forming stable 25

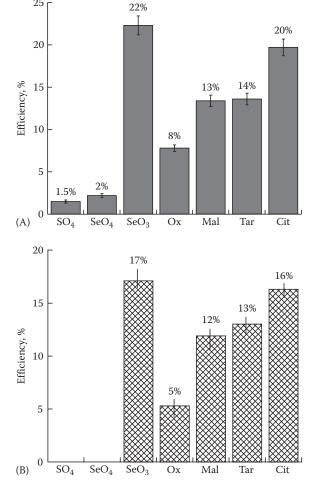

FIGURE 8.4 Influence of organic and inorganic ligands on the sorption of (A) As(III) and (B) As(V) onto ferrihydrite. Arsenite or As(V) and ligands were added together and at an initial molar ratio of As/ligands = 1 at pH 6.0. (Modified from Zhu, J., M. Pigna, V. Cozzolino, A.G. Caporale, and A. Violante. 2011. Sorption of arsenite and arsenate on ferrihydrite: Effect of organic and inorganic ligands. J. Hazard. Mater. 189:564–571.)

dissolved or dispersed negatively charged complexes with the cations (Violante et al., 2008). McBride (1991) showed that various LMMOAs (phthalate, fulvate, and citrate) strongly inhibit the sorption of Cu (Figure 8.5) by montmorillonite.

However, the presence of certain foreign ligands, occurring naturally in the rhizosphere, such as siderophores produced by microorganisms and phytosiderophores exuded by plants, may promote the sorption of trace elements onto phyllosilicates. They may also help to modify the mobility and then the phytoavailability of trace elements at the soil-root interface. Neubauer et al. (2000, 2002) studied the influence of hydroxamate siderophore desferrioxamine-B (DFOB) on the sorption of Zn onto montmorillonite (Figure 8.6A) and ferrihydrite (Figure 8.6B). DFOB showed a strong affinity for montmorillonite at pH < 7.5(not shown). At low pH and in the absence of DFOB, only small amounts of Zn were sorbed on montmorillonite (Figure 8.6A), but increasing pH, sorption of Zn increased, and especially at pH > 8.0. In the presence of DFOB (DFOB/Zn molar ratio of 4),

Processes of heavy and transition metal sorption by soil minerals, p. 149-176. In G.H. Bolt, M.F. De Boodt, M.H.B. Haynes, and M.B. McBride (eds.) Interactions at the soil colloid-soil solution interface. Vol. 190. Kluwer Academic Publishers, Dordrecht, the Netherlands.).

Zn sorption edge was shifted to lower pH values, maximum sorption being reached at about pH 7 (Figure 8.6A). Electrostatic interactions are responsible for enhanced Zn sorption onto montmorillonite. The positively charged Zn-DFOB complexes $(MeLH_2^+)$ are the dominant species at about pH 7.

The processes, which affect the sorption of trace element cations onto variable charge minerals in the presence of complexing agents, are particularly complex. Complexing ligands may prevent sorption of trace element cations by forming soluble complexes or by being sorbed onto the surfaces of these minerals blocking some sorption sites or facilitating their sorption, under certain conditions, by decreasing the positive charge of the sorbents. Enhanced sorption has been observed for Cd, Cu, and Zn on Al and Fe oxides in the presence of sulfate or of phosphate (Bolland et al., 1977; Kuo, 1986) due to the increased negative charge brought to the surfaces by these inorganic ligands, whereas high levels of phosphate sorption on a noncrystalline metal oxide inhibited Cu sorption, probably due to blocking of surface sites (McBride, 1985). According to many authors (McBride, 1989; Jackson, 1998, and references therein), some ligands enhance trace element sorption on oxides of Al, Fe, and Si by forming stable surface-metalligand complexes (ternary complexes).

Certain siderophores (e.g., DFOB) strongly affect the sorption of heavy metals onto variable minerals, but their behavior is different from that of LMMOAs. Neubauer et al. (2002) found that DFOB strongly prevented Zn sorption on ferrihydrite (Figure 8.6B), because positively charged DFOB complexes were dominant up to pH 8.0. Because the complexes are not attracted by the positively charged ferrihydrite, DFOB decreased sorption of Zn, in contrast to montmorillonite suspensions (as discussed before; Figure 8.6A).

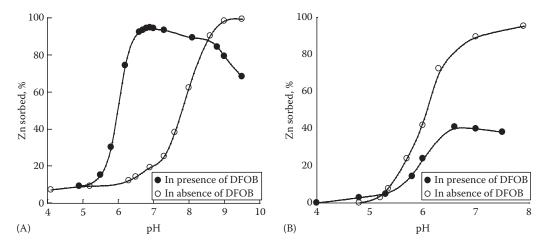

FIGURE 8.6 Sorption of Zn on (A) montmorillonite and (B) ferrihydrite as a function of pH in the absence and presence of DFOB. Dissolved concentration of Zn in montmorillonite suspension was $87.5 \,\mu$ mol L⁻¹ without and with $350 \,\text{mM}$ of hydroxamate siderophore desferrioxamine-B (DFOB), whereas concentration of Zn in ferrihydrite suspension was $10 \,\text{mmol}$ L⁻¹ without and with $300 \,\text{mM}$ DFOB. (Modified from Neubauer, U., G. Furrer, and R. Schulin. 2002. Heavy metal sorption on soil minerals affected by the siderophore desferrioxamine B: The role of Fe(III) (hydr) oxides and dissolved Fe(III). Eur. J. Soil Sci. 53:45-55.)

Organic and inorganic ligands with a high affinity for Fe, Al, and Mn strongly interact with variable charge minerals and soils and then affect the sorption of trace elements in anionic form by competing for available sorption sites and/or reducing the surface charge of the sorbents (Barrow, 1992). The competition depends on the affinity of the anions for the surfaces of the sorbents as well as the nature and surface properties of the minerals and soils.

Smith et al. (2002) studied the effect of phosphate on the sorption of arsenate and arsenite by an Oxisol, a Vertisol, and two Alfisols. The presence of phosphate (0.16 mmol L^{-1}) greatly decreased arsenate and arsenite sorption by soil containing low amounts of Fe oxides (<100 mmol kg^{-1} : Alfisols. Figure 8.7A and B), indicating competitive sorption between phosphate and arsenate or arsenite for sorption sites. In contrast, the presence of a similar amount of phosphate had a much lower effect on the amount of arsenate or arsenite sorbed by Oxisols with high iron content (>800 mmol kg^{-1} : Figure 8.7C and D).

The influence of different organic and inorganic ligands (sulfate, selenite, selenate, malate, tartrate, and citrate) in preventing the sorption of As(III) and As(V) onto ferrihydrite at pH 6.0 and ligand/As(III) or As(V) molar ratio of 1 has been studied (Figure 8.4). Sulfate and selenate poorly prevented As(III) and As(V) sorption, whereas phosphate (not shown) and selenite showed the highest efficiency. All the ligands showed a stronger capacity in preventing As(III) than As(V) (Figure 8.4). Furthermore, the capacity of the ligands in inhibiting As(III) sorption in comparison to As(V) sorption was much greater when a noncrystalline Al-oxide or a volcanic ash soil containing high amounts of allophane were used as sorbents (not shown).

Balistrieri and Chao (1987) suggested that for a given anion concentration ratio, the competition sequence with selenite on goethite is phosphate > silicate > citrate > molybdate > bicarbonate/carbonate > oxalate > fluoride > sulfate. Dynes and Huang (1997) showed that the ability of 12 LMMOAs to inhibit selenite

sorption on poorly crystalline Al-hydroxides was oxalate > malate > citrate > succinate > glycolate > aspartate > salycilate > p-hydroxybenzoate > glycine = formiate = acetate.

There are many reports in published literature showing the effect of competitive anions on oxyanion sorption by LDHs (Goh et al., 2008, and references therein). The effect of competing anions on Cr(VI) and Se(IV) sorption follows the order $CO_3^- > Cl^- >$ water and $HPO_4^- > SO_4^{2-} > CO_3^{2-} > NO_3^-$, respectively. The influence of different ligands on As(III) and As(V) sorption by LDHs is generally in the order $HPO_4^- > SO_4^{2-} > HCO_3^- > F^- > Cl^- > Br^- > NO_3^-$ and order $HCO_3^- > HPO_4^{2-} > SO_4^{2-} > Cl^-$ (Goh et al., 2008).

As reviewed by Violante et al. (2008), the scientific evidence indicates that the ligand–metal ratio, nature of organic and inorganic ligands and trace elements, and surface properties (surface area, crystallinity, PZC) of the sorbent are apparently critical in determining whether trace element sorption at surfaces is enhanced or inhibited. Future in-depth research on this subject matter at a molecular level is warranted.

8.3.7 Desorption of Metal(loid)s

Sorbed metals and metalloids may be desorbed under favorable conditions, but their desorption is often slow, difficult, and incomplete; these metals and metalloids enclosed in oxide precipitates are probably released only if the precipitates are solubilized. In contrast to sorption studies relatively little information is available on the desorption of metals and metalloids from soils or soil components as affected by organic and inorganic ligands, in spite of the wide occurrence of these reactions in soil environments particularly in the rhizosphere (Hinsinger and Courchesne, 2008; as discussed below).

Many studies have shown biphasic reaction processes for desorption of metals and metalloids (Sparks, 1989, 2003); a fast

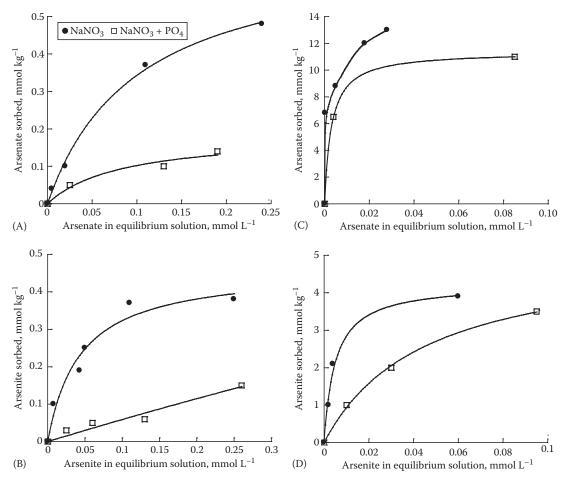

FIGURE 8.7 Arsenate sorption (mmol kg^{-1}) on Alfisol (A) and on Oxisol (C) and arsenite sorption (mmol kg^{-1}) on Alfisol (B) and on Oxisol (D) in the presence of sodium nitrate or sodium nitrate + phosphate (PO₄). (Redrawn from Smith, E., R. Naidu, and A.M. Alston. 2002. Chemistry of inorganic arsenic in soils: II. Effect of phosphorus, sodium, and calcium on arsenic sorption. J. Environ. Qual. 31:557–563.)

reaction is followed by a slow reaction. Presence of inorganic ligands, such as phosphate, has a significant impact on the desorption of metals and metalloids. Krishnamurti et al. (1999b) reported the increase in Cd desorption from soils in the presence of phosphate (Table 8.2). The kinetic data on desorption of Cd by phosphate, as related by the amount of Cd released during the initial 30 min reaction period and the overall diffusion coefficients obtained from the desorption kinetics of Cd by 0.1 mol L⁻¹ mono ammonium phosphate from the soils reflect well the phytoavailable Cd in the two soils, as shown by the Cd availability index and the grain Cd content of two durum wheat cultivars, Kyle and Arcola, grown on the two soils (Table 8.2).

The amount of contact time between trace elements and soil sorbents (residence time) can dramatically affect the degree of desorption, depending on the metal and sorbent. Pigna et al. (2006) performed kinetic studies on the sorption of arsenate on to crystalline or poorly crystalline metal oxides (noncrystalline Al-hydroxide $[Al(OH)_x]$, gibbsite, ferrihydrite, and goethite) and its desorption by phosphate at pH 6.0 as affected by the residence time. By adding phosphate immediately after complete sorption of arsenate onto the oxides (50% surface coverage; PO_4 added/ AsO_4 sorbed molar ratio of 4), a much

higher proportion of As(V) was desorbed after 24h of reaction from Al oxides (48%-56%) than from Fe oxides (18%-23%). The amount of As(V) desorbed decreased with increasing residence time. Figure 8.8 shows the percentage of arsenate desorbed by phosphate from a noncrystalline Al-hydroxide and ferrihydrite as affected by residence time. The kinetics of As(V) desorption by phosphate as a function of residence time can be explained best by Elovich kinetic model (Figure 8.9). The decrease in desorption of arsenate by phosphate with increase in residence time was attributed to the rearrangement of arsenate from desorbable into resistant and undesorbable forms. According to Arai and Sparks (2002), the decrease in desorption of As(V) with increase in residence time could be attributed to different aging mechanisms such as a rearrangement of surface complexes (e.g., from bidentate mononuclear complexes into bidentate binuclear complexes) as well as a conversion of surface complexes into aluminum (or iron) arsenate-like surface precipitates (Jia et al., 2006; Borda and Sparks, 2008). Physicochemical processes may also affect the decrease of As(V) desorption with residence time such as sorption reactions on higher energy binding sites, intraparticle diffusion, and penetration in micropores.

TABLE 8.2 Kinetics of Cd Desorption from Soils by Phosphate

	Cd Desorbed in the Initial 30 min Absence of Phosphate Presence of Phosphate		Overall Diffusio				
			Absence of Phosphate	Absence of Phosphate Presence of Phosphate		Grain Cd ^b	
Soil	μmol kg ⁻¹		μmol kg ⁻¹ h ^{-0.5}		$\mu g kg^{-1}$	Kyle	Arcola
Jedburgh	5.5×10^{-3}	57.8×10^{-3}	3.2×10^{-3}	7.9×10^{-3}	10	42	28
Luseland	188.0×10^{-3} 1150.0×10^{-3}		46.7×10^{-3}	80.3×10^{-3}	169	384	159

Source: Modified from Krishnamurti, G.S.R., P.M. Huang, and L.M. Kozak. 1999b. Sorption and desorption kinetics of cadmium from soils: Influence of phosphate. Soil Sci. 164:888–898.

Desorption kinetics of Cd on the soils is influenced by 0.1 mol L⁻¹ mono ammonium phosphate, described by parabolic diffusion model: $q = a + k_d t^{1/2}$, q is the amount of Cd desorbed in time t (hours) and k_d is overall diffusion coefficient, and a is a constant.

^b Cadmium content in the grain of durum wheat cultivars Kyle and Arcola (Krishnamurti et al., 1999a).

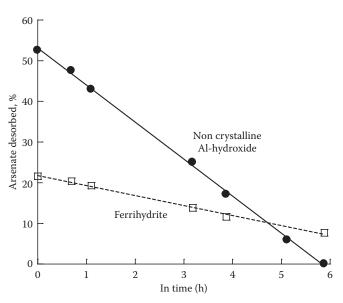

FIGURE 8.8 Arsenate desorbed by phosphate at pH 6.0 from a non-crystalline Al-hydroxide and ferrihydrite. Phosphate was added at initial phosphate/arsenate molar ratio of 4. (Redrawn from Pigna, M., G.S.R. Krishnamurti, and A. Violante. 2006. Kinetics of arsenate sorption-desorption from metal oxides: Effect of residence time. Soil Sci. Soc. Am. J. 70:2017–2027.)

The effect of residence time on Co and Pb desorption from Feand Mn-oxides and soil clays has also been studied. Residence time effect is more evident for Co than Pb. In a soil where 2.1% soil organic matter was present, residence time had little effect on the amount of Pb desorbed, but marked hysteresis was observed at all residences times (Sparks, 2003; references therein).

Coprecipitation of metals and metalloids with Al or Fe in soil environments occurs easily. For example, arsenic accumulation in iron plaques (mainly poorly crystalline precipitates; ferrihydrite) of plant roots has been studied (Liu et al., 2006). Unfortunately, few studies have been carried out on the difference in mobility of metals and metalloids sorbed on or precipitated with metal oxides (Violante et al., 2006, 2007, 2009a). Kinetics studies on the sorption/desorption of As(V) from two samples formed at pH 7.0 and As/Fe molar ratio of 0.1 obtained by coprecipitating Fe and As(V) (7FeR0.1) or by adding As(V) immediately after the precipitation of Fe (7FeAR0.1) were

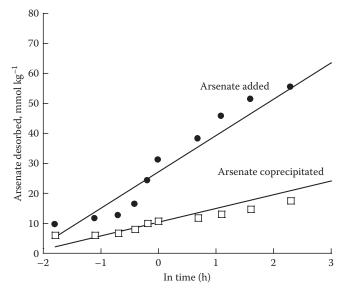

FIGURE 8.9 Kinetics of desorption (Elovich model) of arsenate from 7FeR0.1 (arsenate coprecipitated with iron) and 7FeAR0.1 (arsenate sorbed onto a preformed iron oxide) after addition of phosphate. Phosphate was added at 100% of surface coverage. (Redrawn from Violante, A., M. Pigna, S. Del Gaudio, M. Ricciardella, and D. Banerjee. 2007. Coprecipitation of arsenate with metal oxides: Nature, mineralogy and reactivity of iron(III) precipitates. Environ. Sci. Technol. 41:8275–8280.)

performed by Violante et al. (2007). On these two samples, aged 30 days at 50°C, which had similar surface area (147 and 130 m² g $^{-1}$), phosphate was added in order to have a final surface coverage of 100%. The amounts of As(V) desorbed from the two samples were greatly different, being those desorbed from 7FeAR0.1 (As added) greater than those desorbed from 7FeR0.1 (As coprecipitated; Figure 8.9). However, usually low amounts of As(V) coprecipitated with or sorbed onto Al and/or Fe oxides at pH 7.0 were removed by phosphate (5%-25%), attributed to the formation of strong inner-sphere complexes, metal-As(V) precipitates and partial occlusion of As(V) into the coprecipitates.

Finally, desorption of As(V) as well as other oxyanions previously sorbed onto anionic clays (LDH minerals) merits attention. Recently, Violante et al. (2009b) found that more than 80% of As(V) sorbed on a Mg–Al LDH was replaced by phosphate within 15 days of reaction.

^a Cadmium availability index: mol L⁻¹ NH₄Cl-extractable Cd (Krishnamurti et al., 1995a).

8.4 Biomineralization of Metal(loid)s

The formation of minerals by biological processes, that is, biomineralization, is receiving increasing attention (Dove et al., 2003). Microbial biomineralization of metal and metalloids is an important activity of microorganisms. It involves the transformation of metals and metalloids and the subsequent development of fine-grain minerals of tremendous range and kind (McLean et al., 2002; Huang, 2008). Many metalloids bind with various degrees of tenacity to the largely anionic outer surface layers of microbial cells. Some metals are bound to cell walls to a greater extent than by clay minerals, suggesting that bacterial cell walls and membranes may act as foci for accumulation of metals in soils. Important binding sites on the cell walls and membranes apparently include (1) the phosphodiester group of teichoic acids, (2) free carboxyl groups of peptidoglycan, (3) the sugar hydroxyl group of major classes of wall polymers, and (4) the amide groups of peptide chains.

Specific molecular interactions at inorganic-organic interface can result in the controlled nucleation and growth of inorganic crystals (Mann et al., 1993), resulting in biomineral formation and biomimetic synthesis. A central tenet of biomineralization is that the nucleation, growth, morphology, and aggregation (assembly) of the organic crystals are regulated by organized assemblies of organic macromolecules (the organic matrix). Specific processes involving molecular recognition at inorganic-organic interfaces control over the crystallochemical properties of the biominerals. Electrostatic binding or association, geometric matching (epitaxis), and stereochemical correspondence are involved in these recognition processes. Even subtle differences in the kinetics of these recognition processes on different crystal faces may lead to substantial specific changes in crystal morphology.

Although in most environment, soluble metal(loid) ions are present at low concentration, microbial cells, especially bacterial cells that have the highest ratio of surface area to volume have a remarkable ability to concentrate these ions from solutions (McLean et al., 2002). This leads to the precipitation and formation of mineral phases on their cell walls or surface biopolymers. Bacteria surface layers may serve as a nucleation template for metal(loid)s. Bacteria can also initiate mineral formation by producing reactive enzymes, siderophores, and metallothioneins, which bind metals or catalyze their transformations. Moreover, through modification of the chemistry of the microenvironment, bacteria can instigate the precipitation of metal(loid)s (Douglas and Beveridge, 1998).

Microorganisms may produce inorganic ligands such as sulfide and phosphate as cellular metabolic by-products. Sulfide reacts with metals to form metal sulfides, a common reaction in anoxic environments with sulfate-reducing bacteria (Ehrlich, 2002b). Phosphate pumped out of cells can also react with metal ions to form cell-associated and extracellular precipitates (McLean et al., 2002).

Microbial oxidation of Mn(II) is a major process that can produce Mn oxides in soil environments.

Microbial formation of Mn oxide coating on soil particles can be 10^5 times faster than can abiotic oxidation (Tebo et al., 1997). Manganese oxides are highly reactive minerals that have the ability to restrict the mobility of metals and influence their bioavailability in soil environment. Biogenic Mn oxides have a significantly larger surface area and higher Pb sorption capacity than those of abiotically formed Mn oxides (Nelson et al., 1999).

Biomineralization should thus have global consequences in the dynamics, transformations, toxicity, and fate of metal(loid)s in soil environments. It should merit close attention in the remediation of metal(loid)-contaminated environments.

8.5 Chemical Speciation and Bioavailability of Metal(loid)s as Influenced by Physicochemical and Biological Interfacial Interactions

The biogeochemical cycle of heavy metals and metalloids has been greatly accelerated by human activities. Accumulation of metal ions and metalloids in different compartments of the biosphere and their possible mobilization under environmentally changing conditions induce a perturbation of both the structure and function of the ecosystem and might cause adverse health effects to biota (Fedotov and Mirò, 2008). As a result, heavy metal pollution and the resulting detrimental effects on the environment are widespread throughout the world. A determination of total soil metal content alone is not a good measure of bioavailability and not a very useful tool to quantify contamination and potential environmental and human health risks. Total concentrations of metals in soils are a poor indicator of metal toxicity since metals exist in different solid-phase forms that can vary greatly in terms of their bioavailability (Krishnamurti et al., 1995a, 1995b, 1996; Krishnamurti and Naidu, 2002, 2008; Huang and Gobran, 2005). Most of regulations or guidelines used to protect soil from metal pollution (to set maximum permissible metal concentrations used for definition of contaminated sites, for setting remediation clean-up goals, and for limiting loading of metals to soils in fertilizers and wastes) are still based on assessing the total concentration of metal present in the soil. Recently, some countries have started to introduce the concept of bioavailability in their regulations concerning environmental protection and remediation. The bioavailability of trace metals, their biological uptake, and their ecotoxicological effects on the soil biota can be better understood in terms of their chemical speciation. The mobility and bioavailability and hence potential toxicity of metal in the soil depend on its concentration in soil solution, the nature of its association with other soluble species, and the soil's ability to release the metal from the solid phase to replenish that removed from soil solution by the plants (Christensen and Huang, 1999; Krishnamurti and Naidu, 2002; Huang and Gobran, 2005; Krishnamurti et al., 2007).

A number of chemical equilibrium models are available to predict the solution phase speciation of metals (Loeppert et al., 1995). Solid-phase speciation, however, is particularly important as it determines the rate of replenishment of the metal or metalloid in solution phase and its phytoavailability. The importance of solid-phase speciation has also been stressed in relation to remediation strategies (Krishnamurti, 2000).

8.5.1 Cations

Fractionation of trace metal cations into operationally defined forms under the sequential action of given leachants with increasing aggressiveness is a common approach for distinguishing the operationally defined various species of heavy metals according to their physicochemical mobility and potential bioavailability (Ure and Davison, 2002).

As reported by Fedotov and Mirò (2008) there are two wellaccepted approaches for the classification of the operationally defined fractions. The first one is based on the specific action of the applied reagents. Hence, fractions can be named as "acid soluble," "easily reducible," "easily oxidizable," and so on. These terms are virtually correct and reflect conditions whereby trace elements associated with certain soil (sediment) components can be released. The second approach is based on the mineralogical phases that are supposed to be dissolved under the action of more or less selective reagents. Therefore, fractions can be termed as "elements co-precipitated with carbonates," "elements bound to Mn oxides," "elements bound to Fe oxides," and so on. Though these names are definitely useful for the interpretation of the fractionation results, in some cases, they might lead to misunderstanding because the reagents applied are not highly selective and might cause the shift or overlapping of fractions.

Although sequential extraction scheme, also termed end-overend extraction procedure, has been criticized for each harmonization of procedures, insufficient selectivity of a reagent for a given phase, and/or poor reproducibility, sequential extraction procedures (SEP) are an essential tool for distinguishing trace elements of different solubilities related to mineralogical phases.

During the last 30 years, a few dozens of different SEP have been proposed, but the scheme of Tessier et al. (1979) introduced one of the most popular protocols (Table 8.3A). Sequential

extraction schemes for metal partitioning in environmental solid samples have been recently summarized by Filgueiras et al. (2002).

A more sophisticated SEP, which significantly improved the specificity and efficiency of extraction, by a carefully designed combination of various extractants in order to identify the specific species contributing to bioavailability was proposed by Krishnamurti et al. (1995a). The differentiation of the metalorganic–complex-bound metal species, as distinct from the other organically bound species, was the innovation in the selective sequential extraction scheme suggested by these authors (Table 8.3B). The particulate-bound metal species in soils were fractionated as exchangeable, carbonate-, metal–organic complex-, easily reducible metal oxide-, organic material-, amorphous mineral colloid-, crystalline Fe oxide-bound and residual. The metal–organic complex-bound was selectively extracted using 0.1 M sodium pyrophosphate (pH 10) as the extractant in the sequential extraction scheme.

Krishnamurti et al. (1995a) determined the distribution of particulate-bound Cd species in a few typical soils of southern Saskatchewan, Canada, following the scheme of Tessier et al. (1979) and their modified scheme (Table 8.3B). They found that following the fractionation scheme of Tessier et al. (1979) (Figure 8.10A), an average of 43.2% of Cd in the soils was observed to be in the form Fe, Mn oxide-bound, whereas following their scheme Cd in these soils was predominantly bound to the metal-organic complexes, accounting for an average of 42.4% of the total Cd present in the soils (Figure 8.10B). Krishnamurti et al. (1995a) also found that the Cd in the surface horizons of temperate soils is predominantly present in the form of metal-organic complexbound, accounting for 31%-55%, with an average of 40% of the total Cd present in the soils. According to Onyatta and Huang (1999), the metal-organic complex-bound Cd is also generally the highest among the particulate-bound Cd species of the tropical soils, accounting for 25%-46%, with an average of 37% of the total Cd in the soils. However, in certain tropical soils, residual or crystalline Fe oxide-bound Cd is predominant.

TABLE 8.3 Sequential Extraction Scheme

	A	В			
Species	Extractant	Species	Extractant		
Exchangeabl e	M MgCl ₂ , pH 7	Exchangeable	M Mg(NO ₃) ₂ , pH 7		
Carbonates	M NaOAc, pH 5	Carbonate-bound	M NaOAc, pH 5		
Fe, Mn oxides	NH ₂ OH HCl in 25% HOAc, 95°C	Metal-organic complex-bound	$0.1\mathrm{M}\mathrm{Na_4P_2O_7}\mathrm{(pH10)}$		
Organic	H ₂ O ₂ , pH 2.0, 85°C extract with 3.2 M NH ₄ Oac in 20% HNO ₃	Easily reducible metal-bound	$0.1\mathrm{M~NH_2OH~HCl}$ in $0.01\mathrm{M~HNO_3}$		
Residual	HF-HClO ₄ digestion	$\rm H_2O_2$ extractable organic-bound	$30\%~H_2O_2, pH~2,0$ at $85^{\circ}C$ extract with M Mg(NO $_3)_2$ in $20\%~HNO_3$		
		Amorphous oxides	0.2 M NH ₄ Ox/HOX, pH 3 (dark)		
		Crystalline Fe oxide-bound	$0.2\mathrm{M}$ NH ₄ Ox/HOX, pH 3 in $0.1\mathrm{M}$ as corbic acid; 95°C		
		Residual	$\mathrm{HF} ext{-}\mathrm{HClO}_4$ digestion

(1995a). (Redrawn from Krishnamurti, G.S.R., P.M. Huang, K.C.J. Van Rees, L.M. Kozak, and H.P.W. Rostad. 1995a. Speciation of particulate-bound cadmium of soils and its bioavailability. The Analyst 120:659–665.)

Later, Krishnamurti and Naidu (2000) modified the sequential extraction scheme developed by Krishnamurti et al. (1995a) subfractionating the trace element bound to metal-organic complexes as extracted by 0.1 M sodium pyrophosphate (Table 8.4). This fraction may contain metal associated with both humic and fulvic acid fractions of soil organic matter, which is bound in metal-organic complexes. Following the method suggested by Schnitzer and Schuppli (1989) for separation of metal-fulvate complexes and metal-humate complexes, the metal solubilized by acid (pH 1.0) in the pyrophosphate extracts is termed as metalfulvate complexes and the metal bound strongly to humic acid and that resist desorption at pH 1.0 is termed as metal-humate complexes. These authors have shown that the modified sequential extraction scheme consisting of eight steps of extractions, subdivides the metal-organic complex-bound Cd into metalfulvate complex-bound and metal-humate complex-bound Cd.

Therefore, the scheme fractionates the solid components into specific "species" with operationally defined binding mechanisms, that is, exchangeable, specifically adsorbed/carbonate-bound, metal-fulvate complex-bound, metal-humate complex-bound, easily reducible metal oxide-bound, organic site-bound, amorphous metal oxide-bound, crystalline Fe oxide-bound, and residual (aluminosilicate lattice-bound). Their data indicate that the extraction scheme could be used to identify the specific operationally defined "species" contributing to the bioavailability of the trace element. Details of the extraction scheme are presented in Table 8.4.

The distribution of solid-phase fractions of Cu, Zn, and Cd of a few typical surface soils of South Australia, was carried out by Krishnamurti and Naidu (2000) following the fractionation scheme reported in Table 8.4. The trace elements in these soils were dominantly (on an average 40% of Cu, 52.4% of Zn, and

TABLE 8.4 Multistep Selective Sequential Extraction Scheme for Fractionation of Solid Metal Phases

	Target Species	Reagent	Shaking Time and Temperature
Step 1	Exchangeable	10 mL of M NH ₄ NO ₃ (pH 7)	4h at 25°C
Step 2	Specifically adsorbed	25 mL of M CH ₃ COONa (pH 5)	6h at 25°C
Step 3	Metal-organic complex-bound	30 mL of 0.1 M Na ₄ P ₂ O ₇ (pH 10)	20 h at 25°C
Step 4	Easily reducible metal oxide-bound	20 mL of 0.1 M NH ₂ OH·HCl in 0.01 M HNO ₃	30 min at 25°C
Step 5	Organic-bound	5 mL of 30% H ₂ O ₂ (pH 2), 3 mL of 0.02 M HNO ₃	2h at 85°C
	-	3 mL of 30% H ₂ O ₂ (pH 2), 1 mL of 0.02 M HNO ₃	2h at 85°C
		Cool, add 10 mL 2M NH ₄ NO ₃ in 20% HNO ₃	30 min at 25°C
Step 6	Amorphous mineral colloid-bound	$10 \mathrm{mL} \text{ of } 0.2 \mathrm{M} (\mathrm{NH_4})_2 \mathrm{C_2O_4} / 0.2 \mathrm{M} \mathrm{H_2C_2O_4} (\mathrm{pH} 3)$	4h at 25°C (dark)
Step 7	Crystalline Fe oxide-bound	$25\mathrm{mL}$ of $0.2\mathrm{M}$ (NH ₄) $_2\mathrm{C}_2\mathrm{O}_4/0.2\mathrm{M}$ H $_2\mathrm{C}_2\mathrm{O}_4$ (pH 3) in $0.1\mathrm{M}$ ascorbic acid	30 min at 95°C
Step 8	Residual	Digestion with HF-HClO ₄

A measured quantity of $30\,\mathrm{mL}$ of $0.1\,\mathrm{M}$ Na₄P₂O₇ extract was brought to pH 1.0 with the addition of $6\,\mathrm{M}$ HCl and the suspension was left overnight for the coagulation of humic acid. The suspension was centrifuged at 12,000g for $10\,\mathrm{min}$. Metal-fulvate complexes were determined in the supernatant. The residue was solubilized with $0.1\,\mathrm{M}$ Na₄P₂O₇ and the metal-humate complexes were determined in the solution.

33.4% of Cd) associated with the alumino-silicate mineral lattices, identified as residual fraction in the scheme, followed by the fraction associated with organic sites (on an average 32.4% of Cu, 28.0% of Zn, and 28.5% of Cd) (see Krishnamurti and Naidu, 2008, Figures 11.3 and 11.4).

The mobility and plant uptake of trace elements proceed through the solution phase. However, the plant uptake of an element depends not only on its activity in the solution, but also on the relation that exists between solution ions and solid-phase ions.

An attempt was made by Krishnamurti and Naidu (2002) to understand the importance of solid-phase fractions in assessing phytoavailability of Cu, Zn, and Cd using multiple regression analysis. Phytoavailable Cu, Zn, and Cd were found to be significantly correlated with the metal–fulvate complex-bound Cu (r=0.944, p<0.0001), exchangeable Zn (r=0.832, p=0.002) and the metal–fulvate complex-bound Cd (r=0.824, p=0.002). It was observed that fulvic complex Cu could explain 89% of variation in phytoavailable Cu, whereas the metal–fulvate complex-bound element together with exchangeable element could explain 79% and 92% of variation in phytoavailable Zn and Cd, respectively. Inclusion of solution element concentration in the regression analysis was not found to improve the predictability of phytoavailable element. The regression analysis indicated that the phytoavailable Cu, Zn, and Cd in these soils are mainly from solid-phase fractions.

A number of extractants have been suggested for estimating phytoavailability indices of metals. One of the most commonly used extractant for Cu is the DTPA-TEA soil test (Lindsay and Norvell, 1978) for near-neutral and calcareous soils. Jackson and Alloway (1991) suggested that neutral salts might be the best means available for predicting the bioavailability of trace elements. Krishnamurti et al. (1995a, b) and Krishnamurti (2000) compared a number of extractants for assessing the phytoavailability of Cd and found that M ammonium chloride (NH₄Cl)–extractable Cd had the best correlation with grain Cd of durum wheat.

Recently, Krishnamurti et al. (2007) have studied the mobility and the phytoavailability of cupper on wheat durum (*Triticum durum*) grown in polluted and unpolluted Italian soils. The study was conducted to determine the solid phase distribution of copper in representative soils of Italy with wide differences in the chemical and physicochemical properties. Sites selected varied in location as well as in current vegetation and land use. Samples with a high load of Cu (132–253 mg kg⁻¹) from a

vineyard cultivation area were also included to study the effect of contamination on the distribution of Cu among solid phases. The solid phase fractionation of Cu in the soils was determined using an eight-step selective sequential extraction method (Table 8.4). The results indicated that Cu was dominantly associated with organic binding sites 62.6%-74.8%. The relative importance of the solid-phase fractions in assessing the Cu phytoavailability by durum wheat in a greenhouse setting and the effectiveness of two soil tests, the DTPA-TEA and NH₄Cl extraction method, for predicting the phytoavailable Cu was studied. Most of Cu was retained by roots with very limited translocation to the upper plant parts of wheat. A significant correlation (r = 0.960, p = 0.0001) was found between the plant Cu content and the Cu associated with the metal-fulvate complexes, indicating that the phytoavailable Cu was mainly from the metalfulvate complexes. The contaminated soils had a significantly higher proportion (77%) of Cu associated with organic binding sites, in comparison to that of uncontaminated soil (21.3%), resulting in higher proportion of phytoavailable Cu.

8.5.2 Anions

While there are a large number of SEPs available for metal cations, only limited work has been done on the sequential extraction scheme for trace elements in anionic form. Wenzel et al. (2001) have developed an innovative and simple method for arsenic sequential extraction, which provides the following five extraction steps with reagents gradually stronger (Table 8.5):

- 1. $0.05 \,\mathrm{M} \,(\mathrm{NH_4})_2 \mathrm{SO_4}, 20^{\circ}\mathrm{C} 4 \,\mathrm{h}$
- 2. 0.05 M NH₄H₂PO₄, 20°C—16 h
- 3. 0.2 M NH₄-oxalate buffer in the dark. pH 3.25, 20°C—4h
- 4. $0.2\,M$ NH₄⁺-oxalate buffer + ascorbic acid pH 3.25, $96^{\circ}C$ — $0.5\,h$
- 5. HNO₃/H₂O₂ microwave digestion

These five as fractions appear to be primarily associated with

- 1. Nonspecifically sorbed
- 2. Specifically sorbed
- 3. Amorphous and poorly crystalline hydrous oxides of Fe and Al
- 4. Well crystallized hydrous oxides of Fe and Al
- 5. Residual phases

TABLE 8.5 Sequential Extraction Procedure for Arsenic

Fraction	Extractant	Extraction Conditions	SSR	Wash Step
1	(NH ₄) ₂ SO ₄ (0.05 M)	4h shaking, 20°C	1:25	
2	$(NH_4)H_2PO_4 (0.05 M)$	16 h shaking, 20°C	1:25

Source: Wenzel, W.W., N. Kirchbaumer, T. Prohaska, G. Stingeder, E. Lombi, and D.C. Adriano. 2001. Arsenic fractionation in soils using an improved sequential extraction procedure. Anal. Chim. Acta 436:309–323. Copyright 2001, with permission from Elsevier.

These authors conducted a study using 20 Austrian soils differing in the level of As contamination (from 96 to 218 mg As kg⁻¹) and soil characteristics. The results showed that As was most prevalent in the two oxalate-extractable fractions (30% from step 3 and 27% from step 4), indicating that As is primarily associated with amorphous and crystalline Fe and Al oxides. The fraction of As extracted by NH₄H₂PO₄ represented about 10% of total As and may be useful in providing a relative measure of specifically sorbed As in soils that may be potentially mobilized due to changes in pH or P addition. The amount of readily labile As extracted by (NH₄)₂SO₄ is generally small (0.3%), but may represent the most important fraction related to environmental risks and has been shown to correlate well with As concentrations in field-collected soil solutions.

Recently, Branco (2008), using the method of Wenzel et al. (2001), have studied the sequential extraction of As from polluted Italian soils collected in Scarlino (Tuscany, Italy), which showed a content of arsenic ranging from 100 to 190 mg As kg⁻¹. Figure 8.11 shows the As distribution in La Botte soil. Arsenic was in the most part recovered in the crystalline oxides (59.8%) and short-range Fe and Al oxides (20%). The As fraction extracted with NH₄H₂PO₄ was about 7%, whereas the nonspecifically sorbed (easily exchangeable) fraction that forms outer-sphere complexes onto the mineral surfaces was negligible (<0.2%). The scarce residual As fraction (11%–13%) suggested a low presence of primary minerals rich in this metalloids.

Martin et al. (2007) also used this sequential extraction method for studying the accumulation and potential release of As in a paddy field in Bangladesh irrigated with As-contaminated groundwater. The oxalate-extractable fraction related to amorphous hydrous oxide-bound As represented the dominant As form (47%), and a relatively high amounts of As was removed by phosphate (22%).

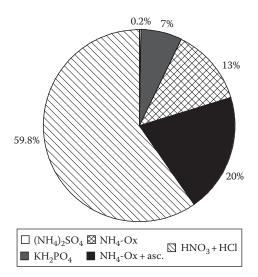

FIGURE 8.11 Arsenate fractionation from one Italian polluted soil (La Botte soil containing 190 mmol kg⁻¹ of As), following the method of Wenzel et al. (2001). (Redrawn from Branco, A. 2008. Mobility and bioavailability of arsenic in Italian polluted soils. PhD Thesis, University of Naples (Italy), Federico II, 122pp.)

8.6 Plant Uptake of Metal(loid)s as Influenced by Physicochemical and Biological Interfacial Interactions

8.6.1 Effects of Plants and Managements

Plants require a range of trace elements (e.g., Cu, Mn, Zn, Mo, Ni) as essential micronutrients for normal growth and development (Kabata-Pendias, 2004). These elements have been acquired in the course of evolution because of their chemical properties such as redox activity under physiological conditions (Cu, Fe) or Lewis acid strength (Zn) (Clemens, 2006). When any of these elements are present in short supply, a range of deficiency symptoms can appear and growth is reduced (Marschner, 1995). However, although essential, these elements can also be toxic when present in excess with the production of reactive oxygen species and oxidative injury being particularly important (Schützendübel and Polle, 2002). The physiological range for essential transition metals between deficiency and toxicity is therefore extremely narrow and a tightly controlled metal homeostasis network to adjust to fluctuations in micronutrient availability is a necessity for all organisms (Clemens, 2006, and references therein). Plants can encounter elevated levels of both essential and nonessential metals. Of major concern with respect to plant exposure as well as food chain accumulation are the metalloids (As and Se), and the metals Cd, Cr, Hg, and Pb (McLaughlin et al., 1999).

Excessive levels of many metal(loid)s can result in soil quality degradation, crop yield reduction, and poor quality of agricultural products, consequently posing significant hazards to human, animal, and ecosystem health. Therefore, the bioavailability of essential and nonessential metal(loid)s has been one of the most crucial problems in agricultural and environmental studies. There has been a steady increase in the number of investigations related to both understanding the processes involved in the uptake of an element (nutrient and non-nutrient) by plants, and to finding the most reliable methods for the prediction of availability of a given element to plants, and in particular to crop plants. Physical-chemical soil parameters such as texture, pH, redox status, content, and quality of mineral components and organic matter modify bioavailability of metal(loid)s (Adriano, 2001). Furthermore, metal(loid)s accumulation in plant tissues is influenced by plant-inherent properties and differ between species, ecotypes, and plant parts (Cobb et al., 2000). Plants differ also in specific root-response mechanisms to environmental conditions such as nutrient availability, bulk density, water content, and presence of toxic elements (Fitz and Wenzel, 2006). The composition of root exudates can greatly change under any environmental stress (Kabata-Pendias, 2004). Plants passively and/or actively modify the rhizosphere, the narrow zone at the soilroot interface. This results in altered chemical, physical, and biological characteristics of the rhizosphere relative to bulk soil. The spatial extension of the rhizosphere can be greatly enlarged by mutualistic symbiosis between plants and fungi, known as mycorrhizas (Marschner, 1995). These plant-induced changes in the rhizosphere may influence the bioavailability of metal(loid)s (Hinsinger and Courchesne, 2008, and references therein).

Metal(loid)s can be depleted or accumulated in the rhizosphere along the gradient that increases or decreases from the root toward the bulk soil, depending on whether their rate of uptake is, respectively, greater or lower than the rate of supply by diffusion and mass flow to the soil–root interface (Marschner, 1995). Besides this effect, the concentration gradients measured in various solid-phase metal(loid) fractions at the soil–root interface can also be attributed to the effects of a variety of processes, such as rhizosphere acidification or alkalinization, adsorption or desorption reactions, and precipitation or dissolution phenomena, which are themselves associated with plant uptake and a range of root activities (Hinsinger, 2001).

Changes in rhizosphere pH values have various origins and can severely alter the speciation of most metal(loi)s both in soil solutions and in the solid phase. Factors affecting rhizosphere pH are the source of nitrogen supply $(NO_3^- vs. NH_4^+ uptake)$, nutritional status of plants (e.g., Fe and P deficiency), excretion of organic acids, CO_2 production by roots and microorganisms, and the buffering capacity of the soil (Marschner, 1995).

Changes in the solubility of Cu in the rhizosphere soil solution was shown in tomato plants grown in an acidic-contaminated soil as a consequence of rhizosphere alkalinization (Hinsinger and Courchesne, 2008, and references therein). Acidification of the rhizosphere of tobacco (*Nicotiana tabacum* L. cv. "SR1") increased Zn in the exchangeable fraction of Zn-contaminated soil (Hinsinger and Courchesne, 2008, and references therein). The behavior of oxyanions such as Mo or As is known to be fairly dependent on pH, via its effect on the surface charge of solids and ultimately on the adsorption–desorption of these oxyanions. For instance, rhizosphere acidification that occurred as a consequence of P deficiency in canola (*Brassica napus* L.) grown on As-contaminated kaolinite resulted in enhanced bioavailability of both phosphate and arsenate, due to enhanced desorption of these oxyanions (Quaghebeur and Rengel, 2004).

Increasing soil water content is associated with the decrease of soil redox potential, which induces various chemical changes in the soil solution due to the decreasing availability of O₂. The oxidation of the rhizosphere is a well-known phenomenon that has been extensively described for lowland rice among agricultural plants. In waterlogged or submerged soils, the leakage of O₂ from the roots, as a consequence of its transfer from the shoots through the aerenchyma (Fitz and Wenzel, 2006), provides an adequate supply of O₂ for rice root respiration. It also enables rice plants to alleviate metal toxicity that can occur due to the ambient reducing conditions of the bulk soil and much increased solubility of metal (Fe and Mn, in particular) oxides under such circumstances (Hinsinger, 2001). Besides, these minerals are known to play an essential role in the fate of metal (loid)s in soils as a consequence of adsorption or coprecipitation processes. Several reports showing the role of the iron plaque, consisting mainly of ferrihydrite, in the sequestration of As clearly demonstrate that root-induced changes of redox conditions can have a dramatic effect on the solid-phase speciation of As in the vicinity of roots (Fitz and Wenzel, 2006).

Oxidation of arsenite, the dominant dissolved species in soil of rice plants, to arsenate favors strong adsorption onto the positively charged iron oxides that form the iron-plaque on roots of lowland rice, although there are some evidence that arsenite adsorption is almost similar to arsenate onto the Fe oxides, particularly onto ferrihydrite (Smedley and Kinniburgh, 2002). In contrast to the above, for those plants living under oxic soil conditions, the availability of Fe is a major constraint given the poor solubility of Fe oxides. The reduction of Fe is a major mechanism involved in the acquisition of Fe by most higher plants (Marschner and Römheld, 1996), where the acquisition of Fe is based on a combination of root-induced acidification and enzymatic Fe reduction (Marschner, 1995). A plasma membranebound reductase system operates the reduction of Fe³⁺ to Fe²⁺, which is supposed to be the only available Fe species in all higher plants except for the monocotyledons. The same is likely true for Mn (Hinsinger, 2001). The resulting root-induced changes of reduction of Fe and Mn are expected to shift the dissolution/ precipitation equilibria of Fe and Mn oxides and promote their dissolution. This should also lead to the concomitant release of metal(loid)s commonly associated (sorbed or included) with these minerals in soil environments. Furthermore, these redox processes are also expected to play a role in mobilization/immobilization processes involving those metal(loid)s that occur in various oxidation states in soil conditions, such as Cr, Cu, and Se (Hinsinger, 2001). The release by plants of organic C in the rhizosphere, rhizodeposition, represents a significant proportion of the net photosynthetic C. The main components of rhizodeposition are LMMOAs, sugars and polysaccharides, proteins, and enzymes. The LMMOAs are a group of compounds that include carboxylic acids (e.g., citric, malic, oxalic), amino acids (e.g., cysteine and glutamine), and phenolic acids (e.g., caffeic). Rhizodeposition is strongly influenced by exogenous conditions and stresses (Hinsinger and Courchesne, 2008). Nutrient deficiency in the soil, mechanical constraints, and limited water supply all stimulate the release of exudates by plants (Nguyen, 2003). These compounds can play a decisive role in controlling metal(loid)s mobilization and hence their bioavailability. Recent studies have elucidated the role of root exudates in the dissolution of Fe oxides (Hinsinger and Courchesne, 2008). They have shown that Fe-complexing compounds can efficiently dissolve Fe from poorly crystalline Fe oxides and goethite, which is a ubiquitous crystalline oxyhydroxide in soils. In Graminaceous species, the phytosiderophores are released by plants in conditions of Fe deficiency as they are involved in the Fe complexation, but they can form chelates with other metals such as Zn, Cu, and Mn and are therefore able to mobilize other micronutrients in case of deficiency (Treeby et al., 1989). There is evidence that in graminaceous plants Fe3+ and Zn2+ can be taken up in the form of nondissociated Fe- or Zn-phytosiderophores (Thomas et al., 2005). Other data suggested that uncharged metal-organic complexes can cross cell membranes (Huang and Germida, 2002). Malinowski

TABLE 8.6 Total As Concentration (μ g kg⁻¹) and Content in Roots, Shoots, and Grain (μ g Pot⁻¹) of Wheat (*T. durum* cv Creso) Exposed to Three As Concentration in Irrigation Water

Source: With kind permission from Springer Science + Business Media: Pigna, M., V. Cozzolino, A. Violante, and A. Meharg. 2009. Influence of phosphate on the arsenic uptake by wheat (*Triticum durum* L.) irrigated with arsenic solutions at three different concentrations. Water Air Soil Pollut. 197:371–380. P⁻ and P⁺ stand respectively for without phosphate fertilization and with phosphate fertilization.

et al. (2004) also reported that Cu was bound to extracellular root exudates, as shown by lower dissolved Cu²⁺ activity in the rhizosphere of tall fescue (Festuca arundinacea Schreb.) grown in a nutrient solution. Besides their impact on the dissolution of metal-bearing mineral phases and on the complexation of metals, organic substances released by roots can also have an impact on the sorption or desorption of metals at the surface of mineral particles. Organic substances released by roots can compete with sorbed anionic species of metals (e.g., chromate) and metalloids (arsenate) and displace them from the exchange complex of soils. On the other hand, soluble exudates can enhance metal sorption through the formation of metal-organic complexes, especially in the lower pH range (Neubauer et al., 2002). In addition, organic compounds released by roots and involved in the complexation of phytotoxic metals have also been reported to reduce the contamination of the plants, such as in the case of Al detoxification by malate or citrate (Ma et al., 2001). Dessurealt-Rompré et al. (2008) indicated that in Lupinus albus, the cluster roots exudation leads on one hand to direct mobilization and complexation of metals like Al, Fe, and Zn by citrate and on the other hand to the mobilization of soil organic matter that complexes and solubilizes Cu and Pb. The complexation of metals by organic substances in the rhizosphere can thus have an entire range of effects and either increase or decrease their bioavailability and phytoxicity (Hinsinger and Courchesne, 2008). Similar to carboxylic acids released by plant roots, inorganic anions such as phosphate may have a significant impact on the sorption/desorption of metal(loid)s in soil environments. Phosphate additions increase extractable fractions of As in batch experiments (Peryea, 1998) and reduced sorption of arsenate and arsenite onto soils (Smith et al., 2002; Violante and Pigna, 2002). Plant uptake of As has been shown to increase upon P application. Peryea (1998) reported increased As solubility and, thus, its phytoavailability on P-fertilizer application to soils. In wheat plants, Pigna et al.

(2009) found that phosphate addition increased As root concentrations but reduced the translocation of As to shoots and grain (Table 8.6).

Rhizosphere microorganisms are key players in the biogeochemistry of metal(loid)s in the rhizosphere. Among them, a prominent role is played by arbuscular mycorrhizal fungi (AMF), which will be discussed in the next section. For future scientific pursuits, it will be necessary to develop a more holistic approach to studying rhizospheric interactions of physical, chemical, and biological processes by integrating advances in microbial and plant ecology and physiology as well as in soil biogeochemistry in order to better predict and eventually manage the mobility and bioavailability of metals and metalloids at soil–root interface.

8.6.2 Effect of Arbuscular Mycorrhizal Fungi on the Transfer of Metal(loid)s to Plants

Soil microorganisms are affected by the presence of high metal concentrations in soil (Gadd, 2005), but the organisms in turn influence the availability of metals in soil either directly, through alterations of pH, Eh, biosorption and uptake, or indirectly in the rhizosphere through their effect on plant growth, root exudation, and the resulting rhizosphere chemistry (Leyval and Joner, 2001).

AMF, phylum Glomeromycota (Schüssler et al., 2001), are one of the most widespread soil microorganisms (Smith and Read, 2008), and constitute an important functional component of the soil–plant system occurring in almost all habitats and climates (Barea et al., 1997), including disturbed soils (McGonigle and Miller, 1996). They form symbiosis with more than 80% of terrestrial plants (Smith and Read, 2008). There has been much interest in the potential use of AMF in agricultural systems by focusing on their ability to improve plant growth through

enhancement of nutrient uptake. Many experiments have demonstrated increased plant uptake of macronutrients P (Smith and Read, 2008) and N (Govindarajulu et al., 2005) as well as micronutrients Cu (Li et al., 1991) and Zn (Bürkert and Robson, 1994) by AMF. The mycorrhizal effect can be explained by mechanisms such as enlargement of the absorption area and volume of accessible soil by extraradical hyphal network, which extends from root surface into soil interstices not accessible to roots and the formation of interfaces (arbuscules, coils, and intercellular hyphae) by the intraradical mycelium, which function as nutrient exchange sites between symbionts (Smith and Read, 2008). They form a direct link between the soil and the root, providing a route for the movement of elements in the mycorrhizosphere.

Inoculation with AMF has been repeatedly reported to modify heavy metals uptake by host plants, but the results are contradictory (Göhre and Paszkowski, 2006). In general, AMF plants are more efficient than nonmycorrhizal in the acquisition of micronutrients such as copper, iron, manganese, and zinc when available at low concentrations (Vosatka et al., 2006). However, when grown in excess of micronutrients or in soils contaminated by metalloids or heavy metals with unknown biological function such as Cd, Cr, or Pb, AM plants can show enhanced metals and metalloids uptake and root-to-shoot transfer (phytoextraction, reviewed by Göhre and Paszkowski, 2006; crop biofortification reviewed by Cavagnaro, 2008) while in other cases AMF contribute to heavy metal immobilization in the soil via fungal metal-binding processes, thereby improving phytostabilization (Joner et al., 2000). Audet and Charest (2007) conducted a literature survey and correlated heavy metal uptake and relative plant growth parameters from published data. They concluded that AM symbiosis increases heavy metal phytoextraction via mycorrhizospheric "enhanced uptake" at low soil heavy metal concentrations, and reduces heavy metals bioavailability via AM fungal "metal-binding" processes at high soil heavy metals levels, hence resulting in increased biomass and enhanced plant tolerance through heavy metals stress avoidance. As predicted by "enhanced uptake" hypothesis, the greater volume of the mycorrhizosphere, compared to the rhizosphere alone, provides an increased access to soil resources, including macro, micro, and even nonessential elements. According to the above-cited study, the mycorrhizospheric impact, accounting for nearly 200% greater heavy metals uptake in AM than non-AM plants at the low soil-heavy metal interval, is likely the result of active soilheavy metals transport to the roots via the extraradical hyphal network (Burleigh et al., 2003; Audet and Charest, 2007), while at high soil-heavy metal interval, the registered nearly 100% lower heavy metals uptake in AM compared with non-AM plants is due to fungal sequestration before transfer to the plant (Joner et al., 2000). The fungus employs strategies similar to those of its host. Among these are immobilization of metals by compounds secreted by the fungus, precipitation in polyphosphate granules in the soil, adsorption to fungal cell walls, and chelation of metals inside the fungus. Glomalin is an example of an insoluble glycoprotein that is produced and released by AMF and binds heavy metals in the soil (Gonzales-Chavez et al., 2004; Göhre

and Paszkowski, 2006). Gonzales-Chavez et al. (2004) found that up to 4.3 mg Cu, 0.08 mg Cd, and 1.12 mg Pb g-1 glomalin could be extracted from polluted soil that had been inoculated with laboratory cultures of AMF. Passive adsorption of heavy metals to chitin in the fungal cell wall reduces also their local concentrations in the soil. Joner et al. (2000) found 0.5 mg Cd per mg dry biomass. The uptake of Pb and its immobilization were found to be higher in roots of mycorrhizal than nonmycorrhizal plants (Chen et al., 2005). The sequestration of Pb in the roots was found to be correlated with an increase in the number of fungal vesicles in highly colonized species. Similar to plant and fungal vacuoles, fungal vesicles may be involved in storing toxic compounds and thereby could provide an additional detoxification mechanism. In soils heavily contaminated with heavy metals and deficient in nutrients, where nonmycorrhizal plant died, the Glomus isolate Br1 obtained from roots of Viola calaminaria, a tolerant plant, allowed plant like maize, barley, and alfa-alfa to grow and complete their life cycle. A nonadaptated isolate of Glomus intraradices also permitted growth but to a lesser extent (Hildenbrandt et al., 1999). An explanation for this observation is offered by another study in maize where it has been found that heavy metals are selectively retained in the inner parenchyma cells coinciding with fungal structures (Kaldorf et al., 1999). A massive accumulation of heavy metals in inner cortical cells of AM colonized maize roots where arbuscules and intraradical hyphae were located was also confirmed using different microbeam techniques (Dosskey and Adriano, 1993). In addition, Wang et al. (2008) showed that in mycorrhizal maize plants As concentrations in external mycelium of two AMF, G. mosseae and Acaulospora morrowiae, increased greatly with increasing As addition level in the growth media, highlighting that the deposition in the external mycelium as the possible role of AMF in the detoxification of As in the host plants. Interestingly, in some cases, mycorrhizal fungi may enhance metal(loid)s resistance in the host plants by effluxing the toxic elements to the external medium. This mode of action was clearly demonstrated by Sharples et al. (2000) who reported that the ericoid mycorrhizal fungus Hymenoscyphus ericae from an As-contaminated site developed arsenate resistance by extruding arsenite into the medium following arsenate uptake, in a similar way to bacteria and yeasts (Rosen, 1999). Apart from the immobilization of metal(loid)s in fungal structure and products, the colonization by AMF can lead to increased uptake and subsequent accumulation of metal(loid)s in above-ground tissues. For example, it was found that addition of AMF further enhances the uptake and accumulation of As in hyperaccumulator fern Pteris vittata (Leung et al., 2006). At the highest As concentration tested (100 mg kg⁻¹ soil), noncolonized plants accumulated 60.4 mg As kg-1 while colonized by AMF isolated from an As mine accumulated 88.1 mg As kg-1. This was accompanied by enhanced growth, possibly due to improved phosphate nutrition reaching 36.3 mg pot⁻¹ in non-colonized and 257 mg pot⁻¹ in colonized plants. Both effects combined allow for higher recovery of metal(loid)s.

The AMF are known to change the chemical composition of root exudates and to affect the activities of soil enzymes, and to introduce physical-chemical modifications to the environment surrounding the roots (Smith and Read, 2008) that can influence the status and availability of metal(loid)s in the rhizosphere. These AMF-induced changes in the rhizosphere and the development of AMF mycelia, which can act as a nutrient source for other microorganisms, are likely to influence the structure and functioning of soil microbial communities in the mycorrhizosphere. Specific modification in the environment between the plant roots and the mycorrhizosphere, such as changes in pH and redox potential, may promote the biotransformation processes of metal(loid)s (Jeffries et al., 2003). Ultra et al. (2007) reported the presence of methylated As species in the rhizosphere of sunflower (Helianthus annuus) plants, grown on As-polluted soil, when inoculated with the AMF *G. aggregatum*. Dimethylarsinic acid (DMMA) was found at low but detectable concentrations in the rhizosphere soil but not in the bulk soil, nor in the rhizosphere soil of uninoculated plants. Mycorrhizal fungi may be able to mediate As biomethylation and release some of the methylated As in the rhizosphere. However, mycorrhizal effects on plant uptake of metal(loid)s can vary depending on certain factors: the fungal genotype, the metal and concentration and availability of metal(loid)s in soil; the plant species and ecotype; and soil edaphic conditions, including soil fertility (Leyval and Joner, 2001). Reduced metal(loid) concentrations in plant tissues of mycorrhizal plants and translocation from plant roots to shoots can be an important factors for quality and safety of plants that enter food chains such as forage crops, medicinal herbs, and vegetables.

The appropriate management of native fungi and/or application of commercial inocula should be chosen according to the cases. However, it should be considered that the effect of mycorrhizal inoculation may interact with fertilization regime as demonstrated for the plants grown in mine tailing containing high levels of Cr (Vosatka et al., 2006, and references therein) or As (Cozzolino et al. 2010). In both cases, plant growth was best after inoculation combined with nitrogen and phosphorus fertilization, whereas neither mycorrhiza nor fertilization alone had any effect on plant biomass. Therefore, mycorrhizal inoculation cannot be considered as panacea and should be combined with other practices such as appropriate fertilization to maximize plant growth and revegetation successes.

8.7 Conclusions and Future Research Prospects

Soil constituents, organic matter, phyllosilicates, variable charge minerals, and microorganisms govern interactive physical, chemical, and biological processes and affect the mobility, bioavailability, and toxicity of metals and metalloids in soil environments.

The sorption/desorption processes of trace elements on/from soil components is affected by many factors, such as pH, nature of the sorbents, redox reactions, presence, and concentration of organic and inorganic ligands, including humic and fulvic

acid, root exudates, and nutrients. The behavior of foreign ligands on the sorption of toxic elements in cationic form is quite different from that toward elements in anionic form. In fact, complexation reaction of trace elements in cationic form with organic and inorganic ligands have an important role on their sorption/desorption processes as well as their toxicity and phytoavailability, whereas competition for available sites and/or reduction of the surface charge of the sorbents between foreign ligands and trace elements in anionic form mainly affect their mobility.

The factors that affect the toxicity or bioavailability of metal(loid)s in soil are still obscure. The dynamics and mechanisms of transformation of metal(loid)s in soil environments and the impact of their mobility, phytoavailability, toxicity, food chain contamination, and ecosystem health should be of increasing concern. Leaching and extraction tests are widely used for assessing trace element mobility and phytoavailability, but the lack of information on speciation and bioavailability in soil arises from the lack of both appropriate techniques for in situ chemical speciation and bioavailability in the field and analytical tools for speciation or fractionation of metal species. Many researchers continue to compare published data without paying much attention to the technique used during speciation. There is therefore a need to standardize speciation and techniques for assessing bioavailability (Krishnamurti and Naidu, 2008). Detailed studies in this area are needed.

Acknowledgments

This study was supported by the Italian Research Program of National Interest (PRIN 2006) and Discovery Grant 2838 of the Natural Sciences and Engineering Research Council of Canada. This paper is dedicated to the memory of Dr. P.M. Huang.

9.1 Introduction

Anthropogenic organic pollutants (AOPs) may be defined as any organic chemical that is foreign to the natural ecosystem, which is released into the natural ecosystem by human activities and may pose adverse effects, either directly or indirectly, on humans and/or other organisms, and on the natural physical, chemical, and biological equilibrium/processes in the environment. Mostly, AOPs are commonly produced and used for the rapid industrialization in agriculture and expansion in various other industries. Emissions of these harmful AOPs have led to local and global deterioration of the environment when they have accumulated in air, water, sediments, soils, and biota, including man (Schwarzenbach et al., 2003). Most of these compounds are hydrophobic organic compounds (HOCs), having attracted a great deal of research interest for more than three decades because of their persistence in the environment and tendency to bioaccumulate. "Hydrophobic" means low water solubility, which is a major factor of HOCs affecting their fate in the environment (Stokes et al., 2006).

Introduction

Besides the direct addition and disposal, AOPs from contaminated air and water may also enter the heterogeneous soil environment via means such as precipitation and agricultural runoffs. The fate and behavior of organic pollutants in soil is governed by soil characteristics, compound properties, and environmental factors such as temperature and precipitation. Possible fates of pollutants entering soil environments include leaching into groundwater, biodegradation, volatilization to air, binding to soil solid phases, and transfer to organisms. Soil can act as a "reservoir" for AOPs in environmental systems because soil has the ability to attenuate AOPs with a large capacity. The "saving" and "discharging" of AOPs in soil, governing the fate of AOPs, are controlled by a series of soil physicochemical and biological interfacial processes. These interfacial processes include sorption-desorption in soil-water interfaces, uptake of plants from soil solution in root-soil interface and rhizosphere, and uptake of soil microbe from soil solution in microbe-soil interface. The "saving" of organic pollutants in soil is controlled by sorption and sequestration from soil solution, while the "discharging" is regulated by desorption to soil solution, and uptake and degradation of plant and soil microbes. Among these processes, sorption and desorption, which decide the bioavailability of organic pollutants and arguably responsible for the majority of biogeochemical processes that occur in soil environment, therefore, play the most important role in the fate of organic pollutants. Furthermore, these interfacial processes can be promoted or restrained by the addition of surfactants in soil environment. The techniques to promote or restrain these interfacial processes are expected to be used in different applications such as remediation of contaminated soils.

This chapter will review these physicochemical and biological interfacial processes that govern the fate of AOPs and the effects of surfactants on these processes, with a particular focus on the sorption-desorption behaviors of organic pollutants in soil-water interface. We will primarily discuss the fate of HOCs in the chapter due to their known toxicity, persistence, and ecological risks. We will start out by a brief introduction of soil system, organic pollutants in soils, typical interfacial behaviors and processes in soil system, and environmental significance of these behaviors and processes for the HOC fate. Following these introductory sections, the main text will address sorption and desorption to or from soil minerals and natural organic matter (NOM), and their complexes. The main text includes three parts: sorption-desorption process in soil-water interface, uptake by plant and soil microbes, and effects of surfactants on typical processes at soil-microbe-plant interfaces.

9.1.1 Soil System

Soil is a heterogeneous, but live system. It is a thin surface layer, covering the bedrock of most of the land area of the earth, and is the final product of the weathering action of physical, chemical, geological, hydrological, and biological processes on parent rocks (Brady and Weil, 1996). Though only a tissue-thin layer compared to the earth's total diameter, to humans and most terrestrial organisms, soil is the most important part of the geosphere and a valuable natural resource that provides the basis of human existence. In addition to being the site of most food production, soil is the receptor of large quantities of pollutants and a key component of environmental chemical cycles (Chiou, 2002).

Scientists widely use the system-modeling approach to look at the processes that operate in a soil because in which a series of inputs, outputs, stores, processes, and recycling of materials and energy can be seen. In a soil system, materials are mostly stored in soil solid particles such as minerals and organic matter by sorption, in organisms such as plants and animals by uptake and accumulation, in soil water by dissolution, and in soil air by volatilization. Furthermore, soils are open and dynamic systems that undergo continual exchange of matter and energy with the atmosphere, hydrosphere, and biosphere. In these systems, materials and energy are gained and lost over time. Any change in the inputs or outputs to the system has a profound effect on the way in which the processes within the soil can operate and, consequently, on the characteristics of the resulting soil. AOPs,

once released into soil, can be distributed in soil components by the processes that operate in the soil. Due to their toxicity, AOPs such as pesticides in soil may damage and kill soil organisms, cause health and ecological risks to humans and most terrestrial organisms by food supply, and contribute to water contamination by leaching and air pollution by volatilization.

A soil system, generally, includes the following main components: mineral particles, organic matter, water, air, and organisms. Figure 9.1 is a simplified presentation of soil compartments. Their proportions vary among different soils due to processes such as translocation, weathering of parent rock, decay and recycling of dead organisms. Even for a single soil, its components change in the layers and over time as well. Basically, soil is a three-dimensional labyrinth of water- or gas-filled pores and soil solid particles with different sizes, forms, and compositions. The small scales and spatial heterogeneity of soil make the estimations of physical and physicochemical conditions that surround pollutants and soil organisms extremely challenging (Chenu and Stotzky, 2002).

Water is part of the three-phase (solid-liquid-gas) system making up soil, which varies geographically with the soil and with the depth in a vertical soil profile. Soil water supports plants and the soil biota (animal and plant life). Water is probably the most important soil component and responsible for most of the translocation of materials such as nutrients from solid soil particles into plants because phase transfers of a chemical in soil are controlled by its dissolved species. The quantity of water in the soil is of critical importance because plants are sensitive to either a deficiency or excess of moisture. Even if there is water in the soil, however, it may not inevitably be available for plant use because water is located in different soil pores, the spaces between the soil particles. Three types of water (i.e., capillary, hygroscopic, and gravitational water) are commonly observed in the soil pores. Due to the negative charged surface of soil particles and the dipoles of water molecules, electro-molecular forces between the soil and water molecules create a thin layer of water with ordered molecules called hygroscopic water surrounding

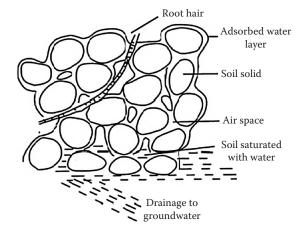

FIGURE 9.1 Fine structure of soil. (Reprinted from Manahan, S.E. 2000. Environmental chemistry. 7th edn. CRC Press, Boca Raton, FL. With permission.)

soil particles (McRae, 1988; Ehrlich, 2002). This water is bound with the inorganic and organic matter to make up the soil, which is held in the soil particles so strongly to prevent its use by plants and does not move as a liquid. Hygroscopic water is surrounded by a layer of capillary water, which may move from one soil particle to another by intermolecular attraction, but not by gravity or hydrostatic pressure (Kuznetsov et al., 1963; Ehrlich, 2002). The capillary water that is found in the soil pores and as layers around each grain of soil is most readily available to plants. When a soil is saturated by water, the excess water (i.e., gravitational water) fills the pore spaces. Gravitational water is commonly observed in big soil pores (bigger than 0.3 µm) and moves freely in soil pores by gravity or hydrostatic pressure (Standing and Killham, 2007). This water is difficult to be used by plant because it easily drains through the soil. The soil pores, which are not filled by water, are generally occupied by soil air. The composition of soil air is regulated by gaseous diffusion and soil respiration because soil pores are not often connected to open atmosphere. Therefore, soil vapor composition varies, but typically soil vapor contains the CO₂ concentration of 0.5%-5.0% and the O₂ concentration of 15%-20% (McRae, 1988).

The principal soil components are minerals and organic matter. The mineral element of the soil is derived from weathered parent rock. Most properties of soil minerals are largely determined by particle size. Particle size distribution determines mineral soil texture (stones >2 mm, sand grains 0.05–2 mm, silt 0.002–0.05 mm, clay particles <0.002 mm) and is often used in the classification of soil (McRae, 1988; Ehrlich, 2002). A decrease of particle size increases soil surface area (Chenu and Stotzky, 2002). Surfaces and edges of soil inorganic particles are often covered with negative charges (McRae, 1988). In most soils, the sand and silt consist largely of grains of resistant minerals, mainly quartz. Clays are composed of aluminosilicates and oxides in various crystalline and amorphous forms.

Soil organic matter (SOM), which originates primarily from biological degradation of plants as well as from animal remains, is composed of plant and animal debris, and intermediates and end-products of the decomposing debris (McRae, 1988). Soil biota is not considered to be a part of the SOM. SOM contains a large amorphous fraction of humus, which has lost most of its original structure and is moderately refractory to biological degradation. The humus fraction, which is soluble in or extractable into aqueous base, is operationally defined humic substance, presenting yellow to brown in color (Stevenson, 1994). The water insoluble and organic solvent soluble part of humus is often referred to as humin or kerogen (Schwarzenbach et al., 2003). The humic substances are further divided into humic acids (HAs) that precipitate at acidic pH and fulvic acids that do not (Ehrlich, 2002; Schwarzenbach et al., 2003). Although the molecular structures of humic substances have not been well characterized and defined, they are known to be a mix of low to high molecular weight amorphous materials containing numerous polar and oxygen-containing functional groups including carboxy-, phenoxy-, hydroxyl-, and carbonyl substituents. The number of such polar groups may vary significantly with the type of soils. Highly polar fulvic acids may have oxygen to carbon (O/C) molar ratios of near 0.5, whereas humin/kerogen has O/C ratios around 0.2–0.3 (Schwarzenbach et al., 2003). Except for relatively rare organic-rich soils, ordinary soils are rich in minerals. The organic matter content for most of these mineral-rich soils falls between 0.5% and 3.0% by weight (Chiou, 2002). In ordinary soils, more than 90% of the dry organic matter is made up of carbon, hydrogen, and oxygen, with minor amounts of nitrogen, sulfur, and phosphorus.

Plants and living organisms are also important in soil system due to their roles in forming SOM. Soil is the habitat of millions of living organisms. These living organisms include bacteria, fungi, and animals such as insects and earthworms. They feed on the complex organic compounds and are responsible for the decomposition of organic materials including organic pollutants.

9.1.2 Soil Pollution and Organic Pollutants in Soils

Soil pollution can be defined as entry of materials, mostly chemicals that are out of place or are present at concentrations higher than normal and have the potential to produce adverse effects on humans and/or other organisms. These adverse effects include the danger of acute toxicity, mutagenesis (genetic changes), carcinogenesis, and teratogenesis (birth defects). Soil pollution is often caused by human activities such as pesticide application and industrial waste materials, leading to the contamination of food grown on the soils. The rapid industrialization of agriculture, expansion of the chemical industry, and the need to generate cheap forms of energy have caused the continuous release of manmade chemicals into natural ecosystems. Consequently, the atmosphere, water, and many soil environments have become polluted by a large variety of toxic compounds. Besides the direct addition of xenobiotic chemicals and disposal of industrial waste materials to soil, AOPs from contaminated air and water may also enter the soil systems by precipitation and agricultural runoffs.

Both inorganic (those that do not contain carbon) and organic (those that contain carbon and hydrogen) chemicals are important contaminants in soil. Inorganic contaminants include inorganic acids, nitrates, phosphates, radioactive substances, and heavy metals such as cadmium, chromium, and lead. The most prominent chemical groups of organic contaminants are fuel hydrocarbons, polycyclic aromatic hydrocarbons (PAHs), polychlorinated biphenyls (PCBs), chlorinated aromatic compounds, detergents, and pesticides. Pharmaceuticals and personal care products including antibiotics, endocrine disrupting chemicals, and veterinary pharmaceuticals are emerging organic pollutants with rising concerns in most recent decade due to their adverse effects on wildlife and human (Daughton and Ternes, 1999). Most of these organic compounds are HOCs. They are at high concentrations and resistant to physical, chemical, or biological degradation in the environment, and thus follow prolonged exposure to humans and other organisms and represent an environmental burden of considerable magnitude. Measurements of levels of HOCs such as PCBs in soils that have been archived for several decades provide interesting insight into the contamination of soil and subsequent loss of these substances from soil (Alcock et al., 1993). For PAHs, it was observed that soils can be contaminated with between $1\,\mu g$ kg $^{-1}$ and $300\,g$ kg $^{-1}$, depending on the sources of contamination (e.g., old coal gasification sites have the higher levels) (Kanaly and Harayama, 2000).

Soil pollution can lead to the pollution of water (including groundwater and surface water), atmosphere, plant, and soil microorganism through various processes. These processes include leaching into water (groundwater and surface water if contaminated runoff reaches streams, lakes, or oceans), uptake by plant and microorganism that grow on polluted soils, and release into the atmosphere especially by volatilization. Furthermore, these transfer processes can affect the consequent behaviors and fates of organic compounds and lead to serious health risks on human beings and animals through food chains. For example, persistent organic compounds (POPs) that are not water soluble tend to accumulate in plant and microorganism after uptake, and they also tend to accumulate increasingly toward the top of the food chain. Therefore, higher concentrations of POPs are always observed in creatures on the higher level of the food chain. Lake Michigan, as an example, has 2 µg kg⁻¹ of DDT in the water, 14 µg kg-1 in the bottom mud, 410 µg kg-1 in amphipods (tiny water fleas and similar creatures), 3-6 mg kg⁻¹ in fish such as coho salmon and lake trout, and as much as 99 mg kg-1 in herring gulls at the top of the food chain (www.pollutionissues.com/ Re-Sy/Soil-Pollution.html).

9.1.3 Physicochemical and Biological Interfacial Behaviors and Processes in Soil System

An organic compound in the soil can remain as a free phase or distribute among the soil compartments. It can be adsorbed to inorganic or organic particle surfaces, absorbed into organic matter, dissolved to soil water, or vaporized into soil air. In addition, organic molecules dissolved in soil water may move by advection or by diffusion. Diffusion is the only mode of molecular transfer in the hygroscopic and capillary waters (Standing and Killham, 2007). Generally, the transfer of an organic compound from soil particles to other phases such as plants and microorganisms is controlled by the dissolved species and concentration of the compound in soil environments when water is present (Schwarzenbach et al., 2003). This is because soil particles are always surrounded by water films due to their charged surface and the dipoles of water molecules (McRae, 1988; Ehrlich, 2002). Furthermore, soil plants and organisms such as soil bacteria rely on organic and inorganic compounds dissolved in soil water for their nutrition (Chenu and Stotzky, 2002). Therefore, the distribution of an organic compound in soil particles, air, plants, and microorganisms and its transfer among these phases depend strongly on various physicochemical and biological interfacial

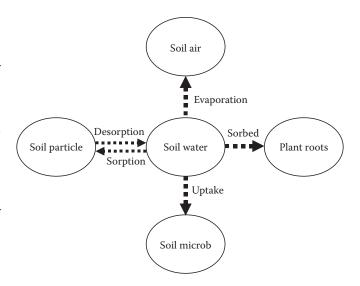

FIGURE 9.2 Physicochemical and biological interfacial behaviors related with soil water.

behaviors related with soil water. These behaviors include sorption-desorption in soil particle-water interface, release to soil air by volatilization from soil water in water-air interface, uptake of plant from soil water in root-water interface, and uptake of soil microorganism from soil water in microbe-soil interface (Figure 9.2).

Distribution of an organic molecule in these interfaces is in a dynamic state. A statistically apparent equilibrium, however, between the concentrations of the organic compound in soil particles and other phases such as soil water can be finally achieved, which helps us to understand the interfacial behaviors of organic compounds and their locations in different soil compartments. Although concentrations of contaminants in soil, water, and other phases in natural systems may deviate from those at equilibrium, the statistical equilibrium data can serve as an essential guide to the direction of contaminant movement at a particular point in time and to the likely consequence of an earlier contamination event. Such information is also valued in elucidating whether a compartment (such as soil particles) functions as a sink (to receive a contaminant) or as a source (to release a contaminant) under a specified condition. Therefore, most studies in this field are often conducted at an equilibrium (or near-equilibrium) condition. The distribution in air-water interface for volatile organic compounds by volatilization, as an example, is well known to be described and estimated by the equilibrium Henry constant. In a soil system, one interface behavior of an organic compound could be affected by another one. For example, uptake of an organic compound by plant root from soil water can be decreased by the sorption of the compound in soil particles from soil water. Among these interfacial behaviors, sorption and desorption, which decide the bioavailability of organic pollutants in contaminated soils and arguably responsible for the majority of biogeochemical processes that occur in soil environment, therefore, play the most critical roles in the fate of organic pollutants.

The understanding of the behaviors of organic compounds at these interfaces can help us to estimate the fate, distribution, transfer, bioavailability, and environmental risks of these compounds in the environment. It can also be of benefit to develop techniques and/or select a technique to alter the distribution and transfer of organic compounds at these interfaces for beneficial purposes. For example, one can select and culture a plant or microbe with high uptake and degradation of organic compounds for the remediation of contaminated soils. Furthermore, we can add an additive to a contaminated soil to enhance the sorption of organic compounds in soil particles to sequestrate them in soil, and consequently decrease its concentrations in soil water and its uptake by plant root for the safety of plant foods that grow on the contaminated soils.

This chapter presents an overview of the physicochemical and biological interfacial processes of nonionic HOCs among soil, water, plant, and microbe because of their environmental significance as described above. The sorption of ionic organic compounds will not be discussed because they constitute a small fraction of all organic contaminants and their most important interfacial process (i.e., sorption by soils) is generally well understood. For example, cationic organic compounds are known to adsorb on soils and clays primarily by a mechanism of cation exchange (Weber et al., 1965; Tahoun and Mortland, 1966), whereas organic anions do not have significant sorption on soils and clays (Harris and Warren, 1964; Weber et al., 1965).

9.2 Sorption-Desorption Process in Soil-Water Interface

9.2.1 History and Development of AOPs in Soil Sorption Studies

Sorption of organic compounds by soil particles is an important distribution process between soil particles and water, controlling the fate, transfer, transport, bioavailability, and eco-environmental risks of these compounds. The distribution of an organic solute between soil particles and water can be described by a soil–water distribution coefficient (K_d),

$$K_{\rm d} = \frac{Q}{C_{\rm c}} \tag{9.1}$$

where

Q is the solute concentrations in soil particles at equilibrium C_e is equilibrium concentration of the solute in water

Studies in this field began in the 1940s for the assessment of the effectiveness and persistence of pesticides in agricultural soils. These studies became more active and intensified in the 1970s for the understanding of the long-term environmental and health risks of organic compounds because wide varieties and large quantities of pesticides and industrial organic wastes were widely found in the environment. It has now come to the characteristics of chemical–soil interactions in terms of soil organic and mineral components and of the properties of organic compounds for the predictions of their sorption behavior under different system conditions.

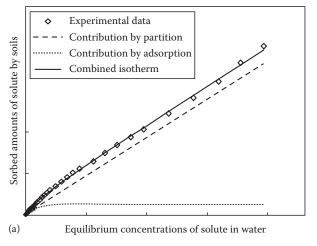

As early as 1968, it was discovered that the SOM was the principal soil component responsible for the sorption of HOCs, showing isotherm linearity (Lambert, 1968). The insignificant sorption of HOCs by soil minerals was explained by the competitive behavior between organic molecules and water on the mineral surfaces with a strong dipole interaction mechanism because the uptake of organic vapors by relatively dry mineral soils and clays was found to be suppressed strongly by soil moisture (Hanson and Nex, 1953; Chiou and Shoup, 1985). A near constant coefficient, named as soil organic carbon content normalized coefficient ($K_{oc} = K_d/f_{oc}$) or SOM content normalized coefficient ($K_{om} = K_d/f_{om}$), can be achieved by normalizing the soil-water distribution coefficients (K_d , the slopes of linear isotherms) to the organic carbon contents (f_{oc}) or organic matter contents (f_{om}) of soils (Karickhoff et al., 1979; Kenaga and Goring, 1980; Kile et al., 1995), where $f_{om} = 1.72 f_{oc}$ based on the common assumption that SOM contains about 58% of carbon content (Hamaker and Thompson, 1972). The organic carbon content normalized coefficients were largely independent on the nature of soils and SOM for a given HOC. Before 1979, SOM was considered as a high-surface-area adsorbent (Bower and Gschwend, 1952; Bailey and White, 1964) and the sorption of HOCs on SOM was explained by hydrophobic interactions (Weed and Weber, 1974; Browman and Chesters, 1977; Mingelgrin and Gerstl, 1983). A concept of partition was suggested by Chiou et al. (1979) to be the controlling mechanism for the HOC sorption in SOM but not the mechanism of hydrophobic sorption on high-surface-area SOM. The term partition refers to a process similar to solution in which an organic molecule penetrates into the entire network of the SOM. Linear relationships between logarithmic K_{oc} , octanol water partition coefficients (K_{ow}) and water solubility (S_{w}) of HOCs were observed (Chiou et al., 1982, 1983). These relationships have been applied simply in the estimation of HOC sorption by soils and further applied in the estimation of bioavailability of HOCs and the engineered design of the remediation of HOC contaminated soils. This concept appeared to work at that time likely because most sorption data were obtained at relatively high concentrations of organic compounds and in a limited sorbent-sorbate contact time. This concept, however, was challenged after 1985 because of the findings such as nonlinear isotherms especially at relatively low concentrations of organic compounds (Weber et al., 1992; Pignatello and Xing, 1996; Xing et al., 1996; Huang et al., 1997; Xing and Pignatello, 1997, 1998; Chiou and Kile, 1998; Chiou et al., 2000), variable K_{oc} values (Rutherford et al., 1992; Spurlock and Biggar, 1994), irreversible sorption (Ball and Roberts, 1991; Pignatello and Xing, 1996; Xia and Pignatello, 2001; Lu and Pignatello, 2004a, 2004b; Sander and Pignatello, 2005b; Sander et al., 2006), and competitive sorption (Pignatello, 1991; Xing et al., 1996; Xing and Pignatello, 1997, 1998; Chiou and Kile, 1998; White et al., 1999; White and Pignatello, 1999; Zhao et al., 2001, 2002).

Irreversible sorption suggested the overestimation of bioavailability of soil sorbed HOCs based on the partition concept and limited the bioremediation potential of contaminated soils (Pignatello, 2006). Furthermore, the concentrations of HOCs in natural environment are commonly in the range of relative low concentrations. The above observations as well as multiphasic desorption kinetics (Ball and Roberts, 1991; Pignatello and Xing, 1996) led to the reconsiderations on the HOC sorption by soils. Soil particles are the complex of SOM, minerals, and other materials such as charcoal and soot, showing heterogeneous nature. These soil components, therefore, may play different roles in the sorption of organic compounds with specific mechanisms, that is, the sorption of organic compounds by soil particles is the combination of those on different soil components with a distributed reactivity. A number of conceptual models such as dual-mode model (DMM) and distributed reactivity model, based on the possible sorption by soil multiple domains, therefore, have been postulated to account for the nonlinear sorption on soils in the past decades. In these concept models, in addition to the partition of HOCs in SOM, adsorption on soil multiple domains was proposed to be responsible for the nonlinear sorption. The term adsorption refers to the condensation of organic molecule on the surfaces or pores of soil particles. The roles of carbonaceous geo-sorbents such as coal, charcoal, kerogen, coke, and soot in the nonlinear adsorption of HOCs were largely studied and presented in detail in several reviews, for example, Cornelissen et al. (2005). To date, sorption by soil particles is commonly explained by the combination of a linear partition mechanism and a nonlinear adsorption mechanism (Weber et al., 1992; Huang et al., 1997; Xing and Pignatello, 1997; Xia and Ball, 1999; Xia and Pignatello, 2001; Chiou, 2002). The combined isotherm (Figure 9.3) shows apparent linearity at relatively high concentrations of an organic compound and nonlinearity at relatively low concentrations.

9.2.2 Partition of HOCs to SOM

9.2.2.1 Characteristics of Partition in SOM

The partition of organic compounds in a partially miscible solvent-water system is an important behavior in chemistry as the basis for solvent extraction of solutes from water. This partition process has been employed by Chiou and co-workers (Chiou et al., 1979, 1983, 1985; Chiou, 2002) to interpret the sorption of HOCs by soils, where the SOM behaves as a partition medium in addition to the recognized dependence of soil sorption on SOM content. Lambert (1967) proposed that SOM functions in HOC sorption analogous to that of a solvent in partition chromatography, showing a correspondence between sorption coefficient and solvent-water distribution coefficient of an organic compound. It was also noted by Swoboda and Thomas (1968) that the linear sorption of parathion by soil might be partly interpreted by a liquid dissolved process in SOM similar to the partition process of the solvent extraction from water. Based on these two works, Chiou et al. (1979, 1983, 1985) developed and advanced the partition concept of HOC sorption in SOM in a series of studies. A set of unique features in the sorption of HOCs by soils and SOM in aqueous systems were found to associate the sorption behavior of HOCs by SOM with the partition concept in these studies. The first one is that the equilibrium isotherms of HOCs are linear at relatively high concentrations (Chiou et al., 1979; Karickhoff et al., 1979; Schwarzenbach and Westall, 1981; Sun and Boyd, 1991; Rutherford et al., 1992), however, linear isotherm for adsorption can be observed only at very low concentrations of HOCs. The second one is that no apparent sorptive competition was found in binary and multisolutes systems (Schwarzenbach and Westall, 1981; Chiou et al., 1983, 1985). The third is that the equilibrium heats of sorption for solutes are less exothermic than heats of solute condensation from water, showing very slight temperature effect on the sorption (Mills and Biggar, 1969; Spencer and Cliath, 1970; Yaron and Saltzman, 1972; Pierce et al., 1974; Chiou et al., 1979). The fourth is that a solute with higher K_{om} or K_{oc} value exhibits lower

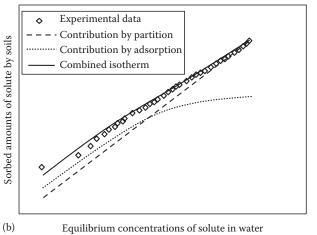

FIGURE 9.3 Schematic plots of contributions by partition and adsorption to the uptake of an organic compound by soils in aqueous system: (a) in normal scale and (b) in log-log scale.

sorption capacity in SOM (Chiou, 1998). For example, the solubility of DDT ($K_{\rm om} \approx 1.5 \times 10^5$) in SOM is about 0.83 g kg⁻¹, which is approximately 40 times lower than that of benzene ($K_{om} \approx 18$) (Chiou, 1998). The fifth one is that negative linear relationships between log K_{om} (or log K_{oc}) and log S_{w} were observed, indicating that water solubility of organic chemicals is the major determinant of their sorption by SOM (Chiou et al., 1979, 1983; Karickhoff et al., 1979; Kenaga and Goring, 1980; Means et al., 1980; Briggs, 1981; Hassett et al., 1981; Karickhoff, 1984). Moreover, the low actual specific surface area (only about 1 m² g⁻¹) of SOM, as measured by the standard Brunauer-Emmett-Teller method with N₂ vapor as the adsorbate (Chiou et al., 1990; Pennell et al., 1995), is far too small to account for solute sorption by SOM with the adsorption mechanism established in the earlier views (Bower and Gschwend, 1952; Bailey and White, 1964; Weed and Weber, 1974; Browman and Chesters, 1977; Mingelgrin and Gerstl, 1983) that SOM was a high-surface-area adsorbent capable of adsorbing HOCs. The high surface area (550-800 m² g⁻¹) for SOM as measured by the ethylene glycol retention method (Bower and Gschwend, 1952), due to the earlier view that SOM was a high-surface-area adsorbent, was shown to be largely an artifact of the high solubility of polar ethylene glycol in relatively polar SOM (Chiou et al., 1990, 1993).

9.2.2.2 Effect of Polarity and Composition of SOM on Partition

Although the normalized partition coefficients (K_{om} or K_{oc}) of a given HOC was expected to be a constant and largely independent on the nature of SOM for the estimation of its sorption, they were observed varied in many studies (Bailey and White, 1964; Goring, 1967; Kenaga and Goring, 1980; Mingelgrin and Gerstl, 1983; Rutherford et al., 1992; Xing et al., 1994; Kile et al., 1995). Part of this variation may be a result of different experimental procedures using different analytical techniques (Bailey and White, 1964; Goring, 1967). Considering the heterogeneous nature of SOM, which contains various compositions and structures, however, the varied partition coefficients $(K_{om} \text{ or } K_{oc})$ can also result actually from the different partitioning abilities of SOM components (Rutherford et al., 1992). Therefore, it is of practical interest to understand how much the SOM medium property affects the partition coefficients $(K_{om} \text{ or } K_{oc})$. This information is critical to whether SOM from different geographic locations and with different humification degrees need to be studied individually (if K_{om} or K_{oc} values vary widely) or can be treated rather indiscriminately (if K_{om} or K_{oc} values are relatively invariant).

Based on the selected $K_{\rm oc}$ data from different reports, Kenaga and Goring (1980) observed that the $K_{\rm oc}$ variation between soils is generally less than a factor of 3–4. However, Mingelgrin and Gerstl (1983) noted that the $K_{\rm oc}$ could vary by as large as a factor of 10 or greater for some pesticides. It has also been observed that kerogen material in SOM has the higher $K_{\rm oc}$ values for phenanthrene than the common humic substances in soils and sediments (Ran et al., 2004). Rutherford et al. (1992) observed

that the partition coefficients (K_{oc} or K_{om}) of organic chemicals such as carbon tetrachloride (CT) have an inverse relation with the elemental weight ratio of [oxygen + nitrogen] to carbon of SOM (Figure 9.4), that is, the (O + N)/C value, an index describing approximately the polarity of SOM. Four relatively ash-free SOM samples including cellulose, muck, peat, and treated peat (peat washed with 0.1N NaOH) were investigated in this study. This inverse relation shows directly the effect of SOM elemental compositions and polarity on solute partition. Utilizing this correlation, Rutherford et al. (1992) noted that the K_{oc} variation of nonpolar organic chemicals between SOM to be less than a factor of 3 if the range of (O + N)/C values for common SOM is considered. Similar correlations between the sorption coefficients (K_{oc}) of phenanthrene and the (O + N)/C values of sequentially extracted soil-derived HAs and humins from a peat were obtained (Kang and Xing, 2005; Yang and Xing, 2009). These inverse correlations indicate that the partition of a nonpolar solute to SOM is sensitive to SOM polarity (or composition) and the polar SOM is a poor partitioning phase for HOCs. Highly humified organic matter such as humin has low polarity and strong partition of HOCs (Kang and Xing, 2005, 2008). The K_{oc} could vary by as large as a factor of 10 between HAs and humins for phenanthrene (Kang and Xing, 2005). This result suggested that HOC sorption was greatly affected by chemical structure and composition of humic substances, even from the same soil. For a more accurate account of the $K_{\rm om}$ or $K_{\rm oc}$ variation in common natural soils and sediments, Kile et al. (1995) measured the K_{oc} values of two relatively nonpolar solutes, CT and 1,2-dichlorobenzene (DCB), on a large set of soils and sediments with significant SOM contents. Thirty-two "normal" soils and 36 "normal" bed sediments collected from diverse geographic locations in both the United States and China were investigated in this

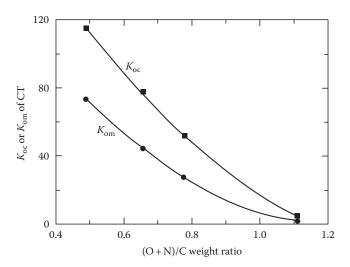

FIGURE 9.4 Plot of the CT $K_{\rm om}$ or $K_{\rm oc}$ value versus the (O + N)/C ratio of natural organic matter. (Reproduced with permission from Rutherford, D.W., C.T. Chiou, and D.E. Kile. 1992. Influence of soil organic matter composition on the partition of organic compounds. Environ. Sci. Technol. 26:336–340. Copyright 1992 American Chemical Society.)

study. The mean K_{oc} value for CT and DCB on 32 normal soils is 60 \pm 7 and 290 \pm 42, respectively. The mean K_{oc} value for CT and DCB on bed sediments is 102 ± 11 and 502 ± 66, respectively, showing a factor of 1.7 greater than that for CT and DCB on soils. The extreme K_{oc} values for soils (or sediments) differ by less than a factor of 2, implying the high degree of invariance of K_{oc} values between most soils or between most bed sediments. This finding reveals firstly that the sediment NOM has a generally lower polarity than SOM, implying that the eroded process of soils into bed sediments brings a noticeable change in the property of the organic composition. A possible cause for this change is that the sedimentation process fractionates SOM such that the more polar and water-soluble organic components in SOM (e.g., fulvic and HA fractions), or that the soil particles with more polar organic components, are separated out to form dissolved organic matter (DOM) and colloids in water, with the less-polar soil organic constituents preserved in the bed sediment (Chiou, 2002). Second, the (O + N)/C values for normal soils should fall into a relatively narrow range to show the similarity in SOM polarity/composition between soils and between bed sediments, according to relatively constant K_{oc} values of CT and DCB on soils from diverse sources ($K_{oc} = 60 \pm 7$ for CT and 290 \pm 42 for DCB). Moreover, the mass ratios of HA to humin for normal soils should vary small based on the large variation of phenanthrene K_{oc} between HAs and humins (Kang and Xing, 2005). The polarity of SOM is often from its polar groups such as -COOH and -OH, as can be obtained from the ¹³C-NMR data of SOM (Kile et al., 1999). From the ¹³C-NMR data of SOM, one can also obtain the aromatic and/or aliphatic fraction contents (Chefetz et al., 2000; Kang and Xing, 2005). With pyrene sorption to SOM varying in chemical composition (e.g., high aliphaticity or aromaticity), Chefetz et al. (2000) observed a positive relationship between the K_{oc} and the aliphaticity of sorbents. Moreover, a comparison between phenanthrene K_{oc} values and paraffinic carbon content of various SOM revealed a positive trend between these two variables in general (Salloum et al., 2002). The conclusion reached by these studies was that aliphatic components in SOM contribute substantially to HOC sorption. Although this positive relationship was also observed for sequentially extracted soil HAs, it failed when humin samples were employed in this relationship (Kang and Xing, 2005). Therefore, polarity of SOM seems to mainly regulate the magnitude of HOC partition rather than structure alone (Kang and Xing, 2008).

9.2.2.3 Effect of Water Solubility and the Polarity of Organic Compounds on Partition

Water solubility, for standpoint of organic chemicals, is the major determinant of their partition into an organic partition medium such as organic solvents. Among the studies of the partition behaviors of organic compounds in various solvent–water systems, the partition between octanol and water is the most used behavior because of the success of *n*-octanol as a surrogate for NOM and/or biological organic components such as lipid. Octanol molecule can mimic some extent of NOM and biological organic

components through its hydrophilic –OH group and lipophilic alkyl chain. Negative linear relationships between octanol–water partition coefficients ($K_{\rm ow}$) and water solubility ($S_{\rm w}$) of HOCs have been observed for the partition of HOCs between octanol and water (Chiou et al., 1982, 1983). SOM has been accepted to be a partition medium for organic compounds in soil–water system (Chiou et al., 1979, 1983). Negative linear relationships between log $K_{\rm om}$ (or log $K_{\rm oc}$) and log $S_{\rm w}$ were also observed in previous works, indicating water solubility is also the major determinant for solute partition into SOM (Chiou et al., 1979, 1983; Karickhoff et al., 1979; Kenaga and Goring, 1980; Means et al., 1980; Briggs, 1981; Hassett et al., 1981; Karickhoff, 1984). Therefore, the solute log $K_{\rm om}$ expresses a linear relationship with solute log $K_{\rm ow}$.

In addition to the dominant effects of water solubility of solutes on their partition into SOM, polarity of solutes can have significant influence on their partition. This solute polarity influence on partition was reflected by the difference of the linear relationships between solute $\log K_{\rm om}$ and solute $\log K_{\rm ow}$ for low-polarity solutes and high-polarity solutes (Figure 9.5). Equation 9.2 gives a linear relationship between $\log K_{\rm om}$ and $\log K_{\rm ow}$ for low-polarity solutes (Chiou et al., 1983), whereas that for high-polarity solutes is given in Equation 9.3 (Briggs, 1981).

For low-polarity solutes

$$\log K_{\rm om} = 0.904 \log K_{\rm ow} - 0.779 \tag{9.2}$$

and for high-polarity solutes

$$\log K_{\rm om} = 0.52 \log K_{\rm ow} + 0.64 \tag{9.3}$$

Compared the slopes and intercepts of Equation 9.3 with Equation 9.2, high-polarity solutes has a much smaller slope but a much larger intercept in the linear relationship between

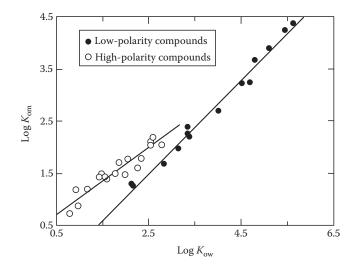

FIGURE 9.5 Plots of $\log K_{\rm om}$ versus $\log K_{\rm ow}$ for low-polarity solutes (Chiou et al., 1983) and high-polarity solutes (Briggs, 1981). (Chiou, C.T. 2002. Partition and adsorption of organic contaminants in environmental systems. John Wiley & Sons, New York. Copyright Wiley-VCH Verlag GmbH & Co. KGaA. Reprinted with permission.)

log $K_{\rm om}$ and log $K_{\rm ow}$ than low-polarity compounds. For low-polarity compounds with log $K_{\rm ow}$ < 7, the $K_{\rm om}$ values are roughly smaller than the corresponding $K_{\rm ow}$ values, suggesting that SOM is not a good solvent for low-polarity solutes as octanol and the SOM polarity is higher than that of octanol. However, SOM is a better solvent for high-polarity solutes than low-polarity solutes, showing the higher $K_{\rm om}$ values of high-polarity solutes than that of low-polarity solutes for a given solute with $K_{\rm ow}$ < 3.8 (Figure 9.5). The polar high-polarity solutes exhibiting a considerably higher partition ($K_{\rm om}$) than the low-polarity solutes in SOM could due presumably to the more powerful molecular interactions between solute and SOM from polar and hydrogen-bond forces over that from London (dispersion) forces (Chiou and Kile, 1994). Moreover, a polar solute could have better compatibility than nonpolar solutes with relatively polar SOM.

9.2.2.4 Effect of Dissolved SOM on Partition

Enhancement of organic solute solubility in water should decrease the solute partition into SOM because partitioning into SOM depends inversely on the water solubility of organic solutes (Chiou et al., 1979, 1983; Karickhoff et al., 1979; Kenaga and Goring, 1980; Means et al., 1980; Briggs, 1981; Hassett et al., 1981; Karickhoff, 1984). It is known that dissolved or suspended SOM in water is able to significantly enhance the water solubility of organic compounds especially for extremely insoluble ones (Wershaw et al., 1969; Carter and Suffet, 1982; Gschwend and Wu, 1985; Chiou et al., 1986). For example, Wershaw et al. (1969) observed that the solubility of DDT in the water solution containing 0.5% SOM is more than 200 times greater than that in pure water (5.5 mg L-1). This solubility enhancement effect expresses a linear correlation between the water solubility of an organic solute in SOM solution (S_w^*) and the dose of SOM in water (X) (Figure 9.6). Solubility of the solute in pure water (S_w) is the intercept of this linear correlation (Figure 9.6). Partition of solutes into the microscopic organic environment of the DOM (Chiou et al., 1986) was suggested to interpret this solubility enhancement. The linear relation between S_w^* and DOM concentration (Figure 9.6), the decrease in solubility enhancement with increasing S_w , and the lack of interference between binary solutes (Figure 9.6), observed by Chiou et al. (1986), are in keeping with the partition interaction between the solute and DOM. Based on the partition theory, one can obtain simply the partition-like coefficient (K_{dom}) of an organic solute distributed between DOM and water to describe the solubility enhancement via the equation established by Chiou et al. (1986), which gives

$$K_{\text{dom}} = \frac{C_{\text{e}}^* - C_{\text{e}}}{XC_{\text{e}}} \tag{9.4}$$

that is,

$$C_e^* = C_e + XK_{\text{dom}}C_e = C_e(1 + XK_{\text{dom}})$$
 (9.5)

where C_e^* includes the solute concentrations in pure water (C_e) and in DOM $(C_e^* - C_e)/X$. If the solute saturated concentration in pure water (water solubility, S_w) is considered for its C_e , the

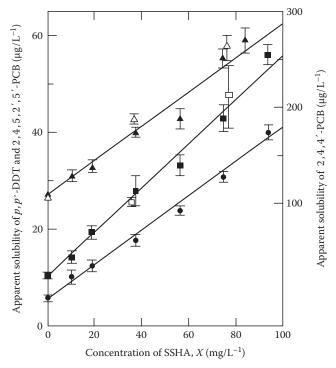

FIGURE 9.6 Apparent water solubility of p,p'-DDT (•), 2,4,5,2'5'-PCB (■,□), and 2,4,4'-PCB (♠,△) as a function of aqueous concentration of Sanhedron soil HA (SSHA) at 24° C- 25° C. Solid symbols are for single solutes; open symbols for the two PCBs are for their binary mixtures. (Reprinted with permission from Chiou, C.T., R.L. Malcolm, T.I. Brinton, and D.E. Kile. 1986. Water solubility enhancement of some organic pollutants and pesticides by dissolved humic and fulvic acids. Environ. Sci. Technol. 20:502–508. Copyright 1986 American Chemical Society.)

apparent solute concentration in water with a given dose (X) of DOM should also be saturated. Therefore, a relationship between the solute saturated concentration in water with a given dose (X) of DOM (S_w^*) and solute saturated concentrations in pure water (S_w) can be established based on Equation 9.5, which gives

$$S_{w}^{*} = S_{w}(1 + XK_{dom}) \tag{9.6}$$

Equation 9.6 represents the linear correlation, as shown in Figure 9.6, between the water solubility of an organic solute in DOM solution (S_w^*) and the dose of DOM in water (X) at the same temperature.

Relating Equation 9.5 with Equation 9.1, one can obtain an apparent soil–water distribution coefficient for the solute (K_d^*) at a given dose (X) of DOM in water, which gives

$$K_{\rm d}^{\star} = \frac{Q}{C_{\rm e}(1 + XK_{\rm dom})} = \frac{K_{\rm d}}{1 + XK_{\rm dom}}$$
 (9.7)

where

Q is the solute concentration in soil particles at equilibrium K_d is the soil–water distribution coefficient for the solute in pure water

According to Equation 9.7, the more SOM dissolved in water, the lower partition of organic solutes into the solid SOM in soil particles. Moreover, the organic solute with higher $K_{\rm dom}$ should express lower partition into the solid SOM in soil particles if DOM is present in water. With $K_{\rm d}=f_{\rm om}K_{\rm om}$ or $K_{\rm d}=f_{\rm oc}K_{\rm oc}$, as defined above for the linear partition of organic solutes into SOM particles, Equation 9.7 turns to

$$K_{\text{om}}^{\star} = \frac{K_{\text{om}}}{1 + XK_{\text{dom}}} \tag{9.8}$$

or

$$K_{\text{oc}}^{\star} = \frac{K_{\text{oc}}}{1 + XK_{\text{dom}}} \tag{9.9}$$

Based on the partition theory, K_{dom} should depend on the type of solute and the composition of DOM. Using a series of solutes with vastly different S_w values and of DOM with varied compositions and structures, Chiou et al. (1986, 1987) examined the effects of solute S_w and DOM composition on K_{dom} . For a given DOM, it was observed that the solute K_{dom} values showed an inverse relation with solute $S_{\rm w}$ values but a positive relation with respective $\log K_{ow}$ values. Solute K_{dom} values become negligible for relatively water-soluble solutes such as lindane and 1,2,3-trichlorobenzene (TCB). An empirical rule, that the concentrations of DOM in water for an enhancement of solute K_{dom} with a factor of 2 must be at least about two orders of magnitude greater than the solute S_{w} , was suggested by Chiou et al. (1986, 1987) for most nonpolar solutes except for PAHs. Because the DOM concentrations in natural water seldom exceed $100 \,\mathrm{mg} \,\mathrm{L}^{-1}$, only those solutes with $S_{\mathrm{w}} < 1 \,\mathrm{mg}$ L⁻¹ could possibly exhibit a significant increase in their concentrations by DOM in natural water. The magnitude of K_{dom} was also observed to depend on the polarity as measured by (O + N)/C and molecular size of DOM (Chiou et al., 1986, 1987). Although DOM such as phenylethanoic acid may have low polarity (70.6% C, 5.9% H, and 23.5% O), they are unable to produce a strong solubility enhancement effect on organic solutes as humic and fulvic acids because of the small DOM size (the molecular weight of phenylethanoic acid is 136.15 g mol⁻¹), in agreement with the required DOM size in DOM partition interaction. However, the molecular size of DOM is not the sole factor determining the solubility enhancement of organic solutes. For example, polyacrylic acid with large molecular size (MW = 2000 and 90,000 g mol-1) and comparable elemental composition (50% C, 5.6% H, and 44.4% O) with natural DOM, has not shown solubility enhancement effect on organic solutes (Chiou et al., 1986). The inability of polyacrylic acid in solute solubility enhancement is attributed to the frequent and orderly attachment of hydrophilic carboxyl groups to the carbon chain and to an extended chain structure, which prohibit the formation of a sizable intra-molecular nonpolar environment. Therefore, in order to promote partition interaction with organic solutes, the DOM molecules must possess both a favorable size of nonpolar moiety and a sufficiently large molecular weight.

In addition to the DOM polarity and molecular size, the DOM aromatic content could significantly influence on the solubility enhancement of aromatic chemicals such as PAHs. For example, Chin et al. (1997) found that the magnitude of solubility enhancement of pyrene, by a series of DOM with minor differences in oxygen content, has a good correlation with the DOM aromatic contents and its molecular weight. Furthermore, the $K_{\rm dom}$ value of pyrene by the dissolved Aldrich HA (a commercial HA with a very high aromatic content) is only about a factor of 2 smaller than that of DDT, whereas the $K_{\rm ow}$ value of DDT is about 15 times higher that of pyrene (Chin et al., 1997). The π - π interactions between DOM and PAH aromatic moieties may play an important role in the solubility enhancement of PAHs (Gauthier et al., 1987).

On a unit weight basis, the observed K_{dom} values of organic solutes between DOM and water were about half as large as the $K_{\rm om}$ values of the solutes between solid bulk SOM and water (Chiou et al., 1986), suggesting that the configurations of SOM dissolved in water or adsorbed on soil particle surfaces may also play a critical role in the partition. The dissolved SOM in water, similar to surfactants, could be expected to exist as micelle-like aggregates with relatively small size, whereas adsorbed SOM on soil particle surfaces may exist as semi-micelle-like aggregates with relatively large size. Through the interactions such as the hydrogenbond most likely between SOM polar fractions and soil particle surfaces, the long chain fractions of adsorbed SOM on soil particle surfaces can come close together through hydrophobic interaction to form the large aggregates. Therefore, adsorbed SOM aggregates could possess a more favorable nonpolar moiety with a sufficiently large size than the dissolved SOM aggregates for solute partition. However, DOM may be different from the bulk SOM in terms of compositions and structures, which can also result in the difference between K_{dom} and K_{om} .

In soil-water systems, the DOM amount (X) by dissolving SOM in water usually increases with increasing soil-to-water (soil/water) ratio. According to Equation 9.7, the enhanced solute solubility by DOM, therefore, offers a logical explanation to the decrease of solute K_d^* with the increasing soil/water ratio in the soil-water systems observed by Gschwend and Wu (1985). The large variation in $\log K_{\rm om}$ for highly water-insoluble solutes observed by Means et al. (1982) and Karickhoff (1984) could be interpreted at least in part by the different extents of solute solubility enhancement by DOM because various solid/water ratios were used in the sorption experiment. However, the significant effect of enhanced solute solubility by DOM on the decrease of solute K_d^* could be observed only for highly water-insoluble solutes. For relatively water-soluble solutes such as lindane and TCB, this effect may become negligible because their solubility enhancement by DOM is insignificant and the DOM concentrations in natural water are often less than 100 mg L-1 (Chiou et al., 1986, 1987).

9.2.3 Adsorption and Isotherm Nonlinearity

Although the sorption of HOCs by soils commonly shows isotherm linearity especially at relatively high concentrations (C_e/S_w) and is interpreted by the partition-like mechanism of

HOCs into SOM, which is accepted as the partition medium (Chiou et al., 1979; Chiou, 2002), later studies on the HOC sorption by soils and sediments observed the isotherm nonlinearity at relatively low concentrations and the solute concentration-dependent sorption coefficients (Ball and Roberts, 1991; Weber et al., 1992; Spurlock and Biggar, 1994; Xing et al., 1996). This isotherm nonlinearity phenomenon was further proved by the findings such as irreversible sorption (Pignatello and Xing, 1996; Xia and Pignatello, 2001; Lu and Pignatello, 2004a, 2004b; Sander and Pignatello, 2005b; Sander et al., 2006) and competitive sorption (Xing et al., 1996; Xing and Pignatello, 1997, 1998; Chiou and Kile, 1998; White et al., 1999; White and Pignatello, 1999; Zhao et al., 2001, 2002). The chemicals employed in these studies include nonpolar and polar solutes (e.g., phenanthrene, triazines, and trichloroethylene). The isotherm nonlinearity indicates the higher sorption coefficients of solutes at relatively low concentrations compared to the upper linear sorption range. Since the concentrations of organic contaminants in natural environment are often fall into the relatively low concentration range, the linear partition theory may underestimate the adsorbed amount of organic contaminants by soils. Moreover, the irreversible sorption suggested the overestimation of bioavailability of soil sorbed HOCs based on the partition theory and limited the bioremediation potential of contaminated soils (Pignatello, 2006). Therefore, it is of practical interest to examine the cause of such nonlinear sorption for organic solutes at low C_e/S_w .

Considering the heterogeneous nature of soils, a number of conceptual models were postulated to account for the observed isotherm nonlinearity on soils: (1) the unsuppressed adsorption of polar solutes by water on certain soil minerals could result in nonlinear sorption at low C_e/S_w (Laird et al., 1992; Haderlein and Schwarzenbach, 1993; Haderlein et al., 1996; Weissmahr et al., 1997; Chiou and Kile, 1998; Chiou et al., 2000; Chiou, 2002); (2) SOM was considered to be a heterogeneous substance, consisting of two types of domains characterized as "soft carbon, which was envisioned as a highly amorphous and swollen SOM" and "hard carbon, which was envisioned as a condensed and relatively rigid organic matrix" (Huang et al., 1997; Leboeuf and Weber, 1997), where the solute sorption to "soft carbon" SOM is controlled by partition with linear isotherm and that to "hard carbon" portion of SOM is controlled by a surface adsorption with nonlinear isotherm (Weber et al., 1992; Young and Weber, 1995; Huang et al., 1997; Leboeuf and Weber, 1997); (3) SOM was also assumed to be consisted by two structural entities, one in a rubbery state and the other in a glassy state analogous to rubbery and glassy synthetic polymers respectively, where the nonlinear isotherm occurs as a result of the solute adsorption onto the glassy portion of SOM because of the existence of different sets of specific "internal holes" for adsorption, in addition to the linear partition into the rubbery portion of SOM (Pignatello and Xing, 1996; Xing et al., 1996; Xing and Pignatello, 1997); (4) a small amount of carbonaceous material (such as charcoal or soot), or high-surface-area

carbonaceous material (HSACM), exists in soils in addition to SOM, the former exhibiting a greater nonlinear adsorption at relatively low concentrations and SOM responsible for linear partition (Chiou, 1995; Gustafson et al., 1997; Chiou and Kile, 1998; Chiou et al., 2000; Cornelissen et al., 2005); (5) the presence of limited active sites in SOM exhibits specific interactions with polar solutes, which is approaching saturation at lower solute concentrations, in addition to the linear partition to SOM (Spurlock and Biggar, 1994). Later, Chiou and Kile (1998) and Chiou et al. (2000) indicated that the combination of the specific-interaction model for polar solutes and the HSACM model for nonpolar solutes may reconcile the outstanding features of the nonlinear and competitive sorption of the solutes with certain soil samples. However, nonlinear isotherms were observed in black carbon (BC)-free NOM samples (Pignatello et al., 2006). Overall, soil is considered to be a dual sorbent for organic compounds. Sorption of organic compounds by soils can be explained by the combination of a linear partition mechanism and a nonlinear adsorption mechanism as shown in Figure 9.3. Therefore, total sorption by NOM is predominated by partitioning at relatively high concentrations showing isotherm linearity, while predominated by adsorption at relatively low concentrations showing commonly isotherm nonlinearity (Figure 9.3).

9.2.3.1 Adsorption of HOCs on Soil Minerals

In soil-water system, SOM was observed to be the principal soil component controlling the sorption of HOCs, while the sorption of HOCs by soil minerals was insignificant (Lambert, 1967; Saltzman et al., 1972; Karickhoff et al., 1979; Kenaga and Goring, 1980; Kile et al., 1995). The lack of adsorption of polar 2,4-dichlorophenol (2,4-DCP) on montmorillonite and amorphous silicon oxide (Yang et al., 2004), phenol on goethite (Yost and Anderson, 1984), and parathion on clay minerals (Saltzman et al., 1972) indicates also the negligible role of soil minerals in sorption of HOCs by soils. In previous studies, it was observed that the vapor uptake of methyl bromide (Chisholm and Koblitsky, 1943), chloropicrin (Stark, 1948), ethylene dibromide (Hanson and Nex, 1953; Wade, 1954), benzene (Chiou and Shoup, 1985), m-dichlorobenzene (Chiou and Shoup, 1985), and 1,2,4-trichlorobenzene (Chiou and Shoup, 1985) was reduced progressively by increasing soil moisture. The suppression of increasing relative humidity on vapor uptake of m-dichlorobenzene by soil (Chiou and Shoup, 1985), as an example, is given in Figure 9.7. Similar suppression of soil moisture was observed for the uptake of parathion and lindane by soils from hexane solution (Yaron and Saltzman, 1972; Chiou et al., 1985). These observations indicate that water can exhibit strong competition with organic compounds on soil mineral surface, thus, the surface of soil minerals is unavailable for adsorption of organic compounds (i.e., the insignificant sorption of HOCs by soil minerals). Even for polar organic solutes such as 2,4-DCP (Yang et al., 2004) and phenol (Yost and Anderson, 1984), the competitive adsorption of water on soil minerals is also so strong to avoid the adsorption of polar solutes.

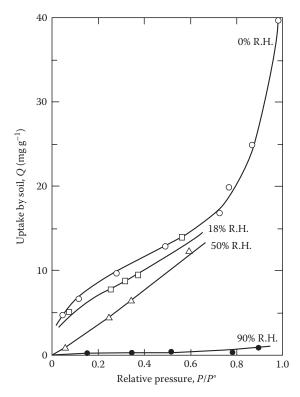

FIGURE 9.7 Vapor uptake of m-dichlorobenzene on dry Woodburn soil as a function of relative humidity (RH) at 20°C. (Reprinted with permission from Chiou, C.T., and T.D. Shoup. 1985. Soil sorption of organic vapors and effects of humidity on sorptive mechanism and capacity. Environ. Sci. Technol. 19:1196–1200. Copyright 1985 American Chemical Society.)

In some cases for polar solutes, adsorption on soil minerals was notably high, even higher than the partition into SOM. For example, Haderlein and Schwarzenbach (1993) and Haderlein et al. (1996) found that a series of polar nitroaromatic compounds (NACs), with electron-withdrawing substituents that are in resonance with the aromatic ring, may adsorb specifically and reversibly to the siloxane surface present in clay minerals such as kaolinite, illite, and montmorillonite. The adsorption of NACs on other natural minerals including aluminum and iron (hydr)oxides, carbonates, and quartz is negligible. Moreover, the affinity of NACs on siloxane surfaces of clay minerals strongly depends on the type of exchangeable cation(s) adsorbed on the siloxane surfaces. For a given clay, the sorption of NACs was relatively high and exhibited notably nonlinear isotherms (Figure 9.8) and competition among NACs (Figure 9.9) when the clay was exchanged with weakly hydrated cations (e.g., K+, Cs+, or NH₄+), while that became negligible when the clay was exchanged with strongly hydrating Na+, Ca2+, Mg2+, and Al3+ ions. The negligible adsorption of NACs on clays exchanged with the latter set of cations is because of the strong hydration interaction between water and strongly hydrated cations on siloxane surfaces, then the clay siloxane surfaces was occupied by water molecules and thereby inaccessible to polar solutes (Weissmahr et al., 1997). The specific adsorption of NACs on siloxane surface of clay minerals

was interpreted by the coplanar electron donor–acceptor interactions between clay's siloxane oxygens as electron-donors and NAC's oxygens as electron-acceptor (Haderlein et al., 1996). The role of hydrogen-bond between siloxane oxygens and NAC's hydrogens may be insignificant (Weissmahr et al., 1997). The capacity of clays saturated with K⁺, for 1,3,5-trinitrobenzene (TNB) adsorption, follows the order montmorillonite > illite >

kaolinite (Figure 9.8), which could be mainly attributed to the areas of siloxane surfaces present in these clays. However, K^+ -saturated illite exhibited less effective than K^+ -saturated montmorillonite for NACs adsorption when normalizing the capacity of TNB (Figure 9.8) to the siloxane surface area of illite $(26\,\mathrm{m}^2~\mathrm{g}^{-1})$ and montmorillonite $(71\,\mathrm{m}^2~\mathrm{g}^{-1})$ (Haderlein et al., 1996). The less effective adsorption of illite could probably be because illite has a much higher charge density on some surface sites to make the surface more hydrophilic.

The significant influence of exchangeable cations on the adsorption of NACs indicates that the sites on siloxane surface are only accessible for NACs when these sites are occupied by weakly hydrated cations. On this basis, the high adsorption of atrazine by Ca2+-saturated smectites with low cation exchange capacity, as observed by Laird et al. (1992), may be attributed to the existence of abundance hydration-unaffected sites on siloxane surfaces. The negligible adsorption of 2,4-DCP on montmorillonite and amorphous silicon oxide (Yang et al., 2004), phenol on goethite (Yost and Anderson, 1984) and parathion on clay minerals (Saltzman et al., 1972) could be attributed to the absence of (effective) siloxane surface for minerals, and electronwithdrawing substituents in the aromatic ring for chemicals, particularly for the strongly hydrated cations present on siloxane surfaces. In natural environment, strongly hydrated cations (e.g., Ca²⁺, Al³⁺, Mg²⁺) are usually prevailing. The theory that significant adsorption of polar organic solutes on soil/sediment minerals is based on an assumption that natural soils/sediments are saturated by weak hydrated cations (e.g., NH4+, C5+), which is very unusual for ordinary soils. Neglecting the prevailing effect of strongly hydrated cations present in natural environment may lead to the overestimation of adsorption onto natural minerals and misinterpretation of the importance of mineral phases as the controlling factor of nonlinear sorption for natural soils.

Low adsorption of low-polarity nonionic organic solutes (e.g., lindane, chlorobenzenes, and PAHs) and polar nonionic solutes (1,3-dinitrobenzene and 2,4-dinitrotoluene), from singleand binary-solute solutions, on virtually organic-free (<0.01%) hydrophilic minerals (e.g., silica and alumina) and low-organiccarbon clays (e.g., kaolinite and smectite) was also observed (Boucher and Lee, 1972; Huang et al., 1996; Mader et al., 1997; Hundal et al., 2001; Su et al., 2006). Characteristics for this slight adsorption include: (1) isotherm is linear (Boucher and Lee, 1972; Huang et al., 1996; Mader et al., 1997; Hundal et al., 2001; Su et al., 2006) and exhibits practically no competition between solutes (Su et al., 2006); (2) a short time for solutionsolid equilibrium (Huang et al., 1996); (3) a dependence of the adsorption coefficient (K_d) on the mineral surface area (Huang and Weber, 1997) and solute water solubility (Mader et al., 1997); (4) no marked effect of solution pH, ionic strength, and solid surface charge and its sign on the adsorption of nonpolar solutes (Mader et al., 1997; Su et al., 2006), while a significant effect of ionic strength and pH on the adsorption of polar solutes (Su et al., 2006); and (5) low exothermic heats compared to the solute condensation heat from water (Huang and Weber, 1997; Su et al., 2006). The adsorption of nonpolar solutes was

suggested to happen presumably by London (dispersion) forces onto a water film above the mineral surface rather than the mineral surface directly, while that of polar solutes is also assisted by polar-group interactions in addition to London forces (Su et al., 2006). The reduced adsorptive forces of solutes with hydrophilic minerals, which is responsible for the low solute adsorption, are due to the physical separation by the water film above the mineral surface (Su et al., 2006). The low fractions of the water-film surface covered by solutes offer a theoretical basis for linear solute adsorption, low exothermic heats, and no adsorptive competition (Su et al., 2006). Low adsorption of organic solutes by minerals, as described above, suggests that adsorption on soil minerals may be the major/dominant process if these minerals contains very little or no SOM. However, if soils contain higher SOM, normally higher than 0.1%-0.2%, adsorption on soil mineral/inorganic surfaces may become insignificant compared to the concurrent solute sorption into SOM (Schwarzenbach and Westall, 1981). Therefore, the role of soil minerals in sorption of HOCs by soils could be expected to be negligible because the organic matter content for most soils falls between 0.5% and 3.0% by weight in natural environments. In addition, the linear isotherm and no competition (Boucher and Lee, 1972; Huang et al., 1996; Mader et al., 1997; Hundal et al., 2001; Su et al., 2006), observed for adsorption of solutes on soil mineral surface, indicate that soil minerals in natural environment, when strongly hydrated cations present, cannot be a good candidate accounting for the observed isotherm nonlinearity on soils.

9.2.3.2 Adsorption of HOCs on Carbonaceous Geosorbents

Recently, extensive and nonlinear sorption of HOCs was observed for several inert, rigid, condensed, and aromatic materials with high carbon contents and relatively few polar functional groups (Cornelissen et al., 2005). These materials, named as "carbonaceous geosorbents (CG)" and partly named as "BC" or "HSACM," are distinguishable and identifiable in physically and/or chemically relative to "normal" SOM. They include at least unburned coal, kerogen, coke, cenosphere, soot, char, and charcoal (the remnants of incomplete combustion) (Chiou, 1995; Chiou and Kile, 1998; Chiou et al., 2000; Cornelissen et al., 2005). The observed sorption of HOCs on CG can be highly nonlinear with the Freundlich exponent (n) as low as 0.3–0.7 (Cornelissen et al., 2005). The Freundlich exponent (n) is a common parameter to reflect the isotherm nonlinearity, where linear isotherm is reflected with n = 1 and the isotherm nonlinearity commonly reflected with n < 1. The highly nonlinear isotherm exhibits a tendency, analogous to the adsorption on activated carbon, that a strong solute adsorption on CG at low C_e/S_w and at moderate to high C_e/S_w values this adsorption is largely saturated. Moreover, sorption of many HOCs on CG is 1-3 orders of magnitude higher than that to SOM especially at relatively low concentrations. These HOCs include PAHs, PCBs, polychlorinated dibenzo-p-dioxins/ dibenzofurans (PCDD/Fs), polybrominated diphenyl ethers, the pesticide diuron, benzene and chlorobenzenes, and chlorinated short-chain aliphatic compounds (Cornelissen et al., 2005).

Because the ubiquity of CG in soils and sediments has been identified and quantified (Smith et al., 1973; Griffin and Goldberg, 1983; Masiello and Druffel, 1998; Kleineidam et al. 1999; Cornelissen et al., 2005), CG was suggested to be at least one of the causes of the nonlinear sorption and may significantly affect the adsorption of organic compounds in soils and sediments especially for nonpolar compounds and at low $C_{\rm e}/S_{\rm w}$ values. The formation, properties, quantification and occurrence of CG as well as the adsorption mechanisms of HOCs on CG has been well reviewed by Cornelissen et al. (2005). In addition, CG could be viewed as an extraneous substance in soils rather than as part of SOM, even though it is often counted as part of the soil organic carbon in SOM analysis by high-temperature combustion methods.

Although CG has higher affinity and capacity than SOM for HOC adsorption at low C_e/S_w values, its importance to exhibit the predominate role in nonlinear sorption of HOCs by soils, relative to that of SOM, should largely depend on the amount of CG in soils. The measured median BC contents as a fraction of total organic carbon (TOC) are 9% for sediments and 4% for soils based on the current quantification methods (Cornelissen et al., 2005). In fire-impacted soils, the content of charcoal BC may be exceedingly high up to 30%-45% of TOC (Schmidt et al., 1999). Most CG quantification methods are based on an isolation procedure firstly to remove the non-CG organic matter. However, the current isolation procedures is extremely difficult for complete isolation of small amounts of CG from ordinary soils and sediments (Chiou, 2002), which could lead to an overestimation of the CG contents in soils. Moreover, the coating of humic materials was observed to decrease the HOC adsorption on CG (Sander and Pignatello, 2005a), which thus may reduce the importance of CG on nonlinear sorption, depending on the accessible surface of CG.

9.2.3.3 Importance and Role of SOM in Isotherm Nonlinearity

Although the unsuppressed adsorption of polar solutes on certain clay fractions of low-organic-content soils (Laird et al., 1992; Haderlein and Schwarzenbach, 1993; Weissmahr et al., 1997) and the highly nonlinear adsorption on CG (Cornelissen et al., 2005) could result in nonlinear sorption at low C_e/S_w , the nonlinear isotherms of polar and nonpolar solutes as noted on soils with relatively high SOM contents (Chiou and Kile, 1998; Chiou et al., 2000) and on CG-free SOM (Pignatello et al., 2006) indicate the importance of SOM not only for solute linear partition but also for nonlinear adsorption. Furthermore, the importance of SOM in nonlinear adsorption for ordinary soils and sediments was also shown by the direct relations existed between nonlinear adsorption capacity (described by Q₀ and $Q_0 \cdot b$ in Figures 9.10 and 9.11) and SOM content for both polar 2,4-DCP and nonpolar phenanthrene (Yang et al., 2005a). Nonlinear adsorption was separated from the total sorption based on the successful fitting and accounted by the following simple DMM (Huang et al., 1997; Xing and Pignatello, 1997; Xia and Ball, 1999; Xia and Pignatello, 2001; Yang et al., 2005a)

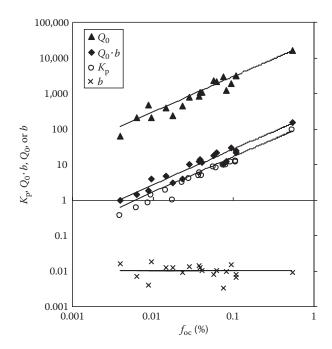

FIGURE 9.10 Values of K_p , Q_0 , b, and $Q_0 \cdot b$ for 2,4-DCP as a function of the organic carbon content f_{oc} of 19 soil/sediment sorbents. (Reprinted from Yang, K., L. Zhu, B. Lou, and B. $$q_{\rm e} = q_{\rm p} + q_{\rm nL} = \frac{K_{\rm p}C_{\rm e} + Q_0 \cdot bC_{\rm e}}{1 + bC_{\rm e}}$$
(9.10)

where

 q_{p} (µg·g⁻¹) depicts the linear partition uptake

 $q_{\rm nL}$ (µg·g⁻¹) depicts the nonlinear adsorption

 K_p (mL·g⁻¹) is the partition coefficient

 C_e (µg·mL⁻¹) is the equilibrium concentration

 $Q_0 (\mu g \cdot g^{-1})$ is the maximum adsorption capacity

 $Q_0 \cdot b \text{ (mL} \cdot g^{-1})$ is the Langmuir-type isotherm slope in the low concentration (Henry's law) range

b (mL \cdot $\mu g^{-1})$ is a constant related to the affinity of the surface for the solute

Nonlinear adsorption of HOCs by SOM was interpreted by a pore filling mechanism in a condensed "hard" glassy-like SOM portion with specific "internal holes" (Weber et al., 1992; Young and Weber, 1995; Pignatello and Xing, 1996; Xing et al., 1996; Huang et al., 1997; Leboeuf and Weber, 1997; Xing and Pignatello, 1997) or the specific interactions between the limited active sites in SOM and polar solutes, approaching saturation at low solute concentrations (Spurlock and Biggar, 1994; Chiou and Kile, 1998; Chiou et al., 2000). In addition, the direct relations between nonlinear adsorption capacity and SOM content indicate that SOM, rather than minerals or CG, predominated the nonlinear adsorption for ordinary soils, in addition to the linear partition to SOM. The unsuppressed adsorption of polar solutes on minerals is negligible relative to the nonlinear adsorption by SOM because of the predominance of strongly hydrated cations (e.g., Na+, Ca2+, Al3+, Mg2+) in natural waters. The reduced influence of CG relative to SOM on nonlinear adsorption may be attributed to the very small amount of CG present in ordinary soils and/or the effect of coated SOM and surface oxidation on the CG.

Because of the predominance of SOM in nonlinear adsorption and linear partition, shown by the linear relationships of $K_{\rm p},\ Q_{\rm 0},\ {\rm and}\ Q_{\rm 0}\cdot b$ with $f_{\rm oc}$ for both polar and nonpolar organic solutes (Figures 9.10 and 9.11), not only $K_{\rm p}$ but also $Q_{\rm 0}$ and $Q_{\rm 0}\cdot b$ for a given organic solute can thus be expressed in terms of the $f_{\rm oc}$ of respective sorbents based on a hypothetical natural sorbent of 100% organic carbon.

$$K_{\rm oc} = \frac{K_{\rm p}}{f_{\rm oc}} \tag{9.11}$$

$$Q_{\rm oc} = \frac{Q_0}{f_{\rm oc}} \tag{9.12}$$

and

$$L_{\rm oc} = \frac{Q_0 \cdot b}{f_{\rm oc}} \tag{9.13}$$

where

 $K_{\rm oc}$ is organic-carbon-content normalized partition coefficient $Q_{\rm oc}$ is organic-carbon-content normalized maximum adsorption capacity

 $L_{\rm oc}$ is organic-carbon-content normalized adsorption coefficient

With this type of treatment, the organic-carbon-content normalized $K_{\rm oc}$, $Q_{\rm oc}$, and $L_{\rm oc}$ for a given organic solute are largely independent on the properties of soils and expected to be largely constant. Variations in $K_{\rm oc}$, $Q_{\rm oc}$, b, and $L_{\rm oc}$ from the difference of organic matter of various soils and sediments were observed for both 2,4-DCP and phenanthrene. However, variations in $K_{\rm oc}$, $Q_{\rm oc}$, and $L_{\rm oc}$ are smaller than those in $K_{\rm p}$, $Q_{\rm o}$, and $Q_{\rm o}$, b, which indicates that $K_{\rm oc}$, $Q_{\rm oc}$, and $L_{\rm oc}$ are the most important characteristic indices for the nonlinear sorption of a given organic solute with soils/sediments. In addition, variations in $K_{\rm oc}$, $Q_{\rm oc}$, and $L_{\rm oc}$ are no greater than variations in $K_{\rm oc}$ reported by different investigators (Briggs, 1981; Schwarzenbach and Westall, 1981; Kile et al., 1995; Yaws et al., 1999).

With the predominance of SOM in nonlinear adsorption, it is also reasonable to observe the influence of SOM composition on isotherm nonlinearity (Chefetz et al., 2000; Xing, 2001a, 2001b; Salloum et al., 2002; Gunasekara and Xing, 2003; Kang and Xing, 2005; Yang and Xing, 2009). For example, it is observed that the isotherm linearity of HOCs by HAs increased with HA aliphaticity (Xing, 2001a; Salloum et al., 2002; Kang and Xing, 2005). Furthermore, Salloum et al. (2002) showed that HA sorption linearity can be increased by reducing the HA aromaticity using chemical oxidation with sodium hypochlorite. These sorption and spectroscopic studies have shown that the condensed (or glassy) SOM portion mainly attributed to SOM aromatic moieties, producing isotherm nonlinearity. The π - π interactions between aromatic moieties of SOM and aromatic compounds such as phenanthrene may play an important role in the nonlinear adsorption of aromatic compounds (Chefetz and Xing, 2009; Yang and Xing, 2009). Therefore, deviation of Q_0 and $Q_0 \cdot b$ from the linear relationships shown in Figures 9.10 and 9.11 could be partly interpreted by the influence of SOM composition and structure on isotherm nonlinearity. The nonlinearity of phenanthrene isotherms on extracted fractions of SOM from a natural soil has an increasing trend with the organic fractions: lipid < fulvic acid < HA < whole soil sample < humin (Liu et al., 2010). SOM configuration may also affect the nonlinear adsorption. For example, Xing (2001b) observed an increasing nonlinearity trend after studying naphthalene and DCB sorption to Florida Pahokee peat and its organic fraction: peat HA < peat < peat humin, which was later explained with the degree of condensed structures expected from organic matter extraction procedures (Cuypers et al., 2002). Gunasekara and Xing (2003) suggested that interaction of SOM with soil mineral surfaces may render the structural configuration of SOM to a more condensed state, which could result in higher nonlinear isotherms of aliphatic-rich humin fractions than HAs (Gunasekara and Xing, 2003; Kang and Xing, 2005). Moreover, the conformation change of SOM may be caused by COOH groups, being oriented in an inaccessible order in a complex with hydrogen-bond acceptors (carbohydrates) contained within SOM (Litvina et al., 2003; Todoruk et al., 2003).

Deviation of Q_0 , and $Q_0 \cdot b$ from the linear relationships may also be from the adsorption on CG (Cornelissen et al., 2005) and the unsuppressed adsorption on certain clay fractions for polar solutes (Laird et al., 1992; Haderlein and Schwarzenbach, 1993; Weissmahr et al., 1997) and the highly nonlinear adsorption on CG, though these adsorption effects on nonlinear sorption may be not dominant for ordinary soils relative to that of SOM because of the predominance of strongly hydrated cations (e.g., Na⁺, Ca²⁺, Al³⁺, Mg²⁺) in natural waters for clays and the very small amount for CG. pH is also considered to affect the nonlinear sorption especially for ionizable chemicals (Westall et al., 1985; Jones and Tiller, 1999).

9.2.3.4 Effect of Solubility and Polarity of Organic Compounds on Nonlinear Adsorption

Negative linear relationships between log $K_{\rm om}$ (or log $K_{\rm oc}$) and log $S_{\rm w}$ were also observed in previous works, indicating water solubility is a major factor for solute partition into SOM (Chiou et al., 1979, 1983; Karickhoff et al., 1979; Kenaga and Goring, 1980; Means et al., 1980; Briggs, 1981; Hassett et al., 1981; Karickhoff, 1984). In a study conducted by Yang et al. (2005b), it was observed that, besides the separated partition coefficients (log $K_{\rm oc}$), the separated coefficients of nonlinear adsorption fraction (log $L_{\rm oc}$ and log b) have also negative linear relationships with the solute log $S_{\rm w}$ (Figure 9.12), suggesting water solubility

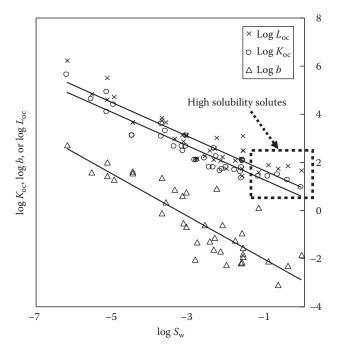

FIGURE 9.12 Values of $K_{\rm oc}$, b, and $L_{\rm oc}$ as a function of solute water solubility $S_{\rm w}$ (mol·L⁻¹). (Reprinted from Yang, K., L. Zhu, B. Lou, and B. Chen. 2005a. Correlations of nonlinear sorption of organic solutes with soil/sediment physicochemical properties. Chemosphere 61:116–128. Copyright 2005a, with permission from Elsevier.)

is another determinant for solute nonlinear adsorption by SOM. The deviation of $\log K_{\rm oc}$ for low solubility solutes from its negative linear relationship (Figure 9.12) is interpreted by the polarity influence on partition (Briggs, 1981; Chiou et al., 1983; Chiou, 2002). Similarly, the deviation of $\log L_{\rm oc}$ for high solubility solutes from its negative linear relationship (Figure 9.12) could also be interpreted by the polarity influence on nonlinear adsorption fraction. The polar solutes with a large water solubility such as 2,4-DCP having a more nonlinear isotherm than the nonpolar and lower solubility solutes, observed by Chiou and Kile (1998), may be an example indicating the effect of water solubility and polarity of organic compounds on nonlinear adsorption.

9.2.3.5 Competitive and Irreversible Sorption

There are many studies (Pignatello, 1991; Xing et al., 1996; Xing and Pignatello, 1997, 1998; Chiou and Kile, 1998; White et al., 1999; White and Pignatello, 1999; Chiou et al., 2000; Zhao et al., 2001, 2002) showing that the nonlinear sorption of a given organic chemical can be reduced in the presence of additional compounds, as shown by the more linear isotherms than that observed in single solute system. The competitive phenomenon has been also observed between organic compounds and naturally occurring aromatic acids (Xing and Pignatello, 1998). Competitive effects are environmentally important because multiple organic pollutants exist far more commonly than single pollutant in natural environments. Competitive phenomenon is one of the important characteristics for nonlinear adsorption against the linear partition (Xing et al., 1996; Xing and Pignatello, 1997). Some important features of competitive effects for nonlinear sorption of solutes, as revealed explicitly by Chiou and Kile (1998), Xing et al. (1996), and Xing and Pignatello (1997), include the following: (1) the suppression of the sorption of a given organic solute at a relatively low concentration by co-solutes is more significant than the solute at a relatively high concentration; (2) the sorption suppression of a given concentration of organic solute by co-solutes is more significant at the relatively high co-solute concentration than that the relatively low concentration co-solute; (3) the sorption suppression of a polar solute (e.g., atrazine) by a nonpolar co-solute (e.g., trichloroethylene) is relatively small, (4) the sorption suppression of a polar solute (atrazine) by other polar co-solutes (e.g., prometon and other triazines) is significant; and (5) the nonlinear sorption of a nonpolar solute could be effectively suppressed by both the polar and nonpolar co-solutes. The results above illustrate that the nonlinear behavior of a given solute in binary- and multi-solute systems is influenced by both the co-solute type and its concentration. Moreover, the polar solutes such as 2,4-DCP are more powerful competitors than nonpolar solutes. A polar co-solute (e.g., 2,4-DCP) of one chemical class may effectively suppress the nonlinear sorption of the given solute of a different class (e.g., diuron) (Chiou and Kile, 1998).

Irreversible sorption phenomenon is also one of the important characteristics for nonlinear adsorption against the linear partition (Xia and Pignatello, 2001; Lu and Pignatello, 2004a, 2004b; Sander and Pignatello, 2005b; Sander et al., 2006).

The term "irreversible" means that the pathways for sorption and desorption are different. The irreversible sorption can be verified by the hysteresis in the isotherm (i.e., the desorption branch deviates from the sorption branch for the isotherm) and the conditioning effect (i.e., the enhanced sorption observed in a repeated experiment on the same sorbent after a prior sorption-desorption cycle). Sander and Pignatello (2005b) have verified the true sorption hysteresis using the isotope exchange technique. By comparing the isotherm on the conditioned soils (pre-contaminated) with that on the respective controlled soil (uncontaminated), conditioning effect on irreversible sorption was also observed (Xia and Pignatello, 2001; Lu and Pignatello, 2004a, 2004b; Sander et al., 2006). Pore deformation mechanism has been suggested to interpret the observed irreversible sorption (Xia and Pignatello, 2001; Lu and Pignatello, 2004a, 2004b; Sander and Pignatello, 2005b; Sander et al., 2006). Irreversible sorption in fact is a result of that a fraction of sorbed solute molecules are fixed in soil to resist desorption. However, many studies have shown that only a small fraction of sorbed pollutants are fixed strongly to resist desorption (Braida et al., 2002; Zhao and Pignatello, 2004). For example, Zhao and Pignatello (2004) observed that the fraction of phenanthrene resisted desorption, after 500-600 days of desorption to infinite dilution, ranged only from about 5%-30% of the initial amount added. A significant amount of irreversible sorption could be an apparent result of slow and time-dependent sorption controlled by sorption-desorption kinetics (Ball and Roberts, 1991; Pignatello and Xing, 1996).

9.2.4 Influence of SOM–Mineral Interactions on Sorption

Although soil minerals including clay and oxides alone, at most time, play a minor role in HOC sorption because of the strong suppression of water on their surfaces (Chiou, 2002; Yang et al., 2004), mineral-SOM interactions commonly result in the HOC sorption by mineral-adsorbed SOM being different from that by bulk SOM (Murphy et al., 1990, 1994; Jones and Tiller, 1999; Gunasekara and Xing, 2003; Wang and Xing, 2005; Feng et al., 2006). For example, mineral-adsorbed SOM commonly exhibits a more nonlinear isotherm than the bulk SOM (Murphy et al., 1990, 1994; Jones and Tiller, 1999; Gunasekara and Xing, 2003; Wang and Xing, 2005; Feng et al., 2006). Fractionation and conformation changes of SOM, which occurs when SOM is adsorbed onto mineral surfaces by mineral-SOM interactions, have been suggested to interpret this difference. The assumptions of fractionation and conformation changes of SOM on HOC sorption could be supported by the observed influence of SOM composition and states on HOC sorption as mentioned in the foregoing analysis. For example, SOM characteristics such as polarity, aromaticity and/or aliphaticity have been observed to affect HOC sorption significantly (Rutherford et al., 1992; Xing et al., 1994; Chefetz et al., 2000; Salloum et al., 2002; Gunasekara and Xing, 2003; Kang and Xing, 2005; Yang and Xing, 2009). SOM fractionation is reasonable because SOM is a mixture of complex molecules, and, thus, some fractions of SOM may preferentially adsorb to the inorganic surface, which results in the adsorbed SOM as well as its HOC sorption affinity being different from the original bulk one and the unadsorbed fractions remaining in solution (Jones and Tiller, 1999; Wang and Xing, 2005). SOM conformation changes, that is, the configuration of adsorbed SOM being different from the respective bulk SOM, was used to further explain HOC sorption difference between the adsorbed HA and the respective bulk HA because this HOC sorption difference cannot be explained by HA fractionation alone in some cases (Murphy et al., 1990, 1994; Jones and Tiller, 1999; Gunasekara and Xing, 2003; Wang and Xing, 2005; Feng et al., 2006).

To explain the nonlinearity of SOM, an expanded SOM domain, analogous to rubbery synthetic polymers, is characterized to generate linear partition, while the condensed SOM domain, analogous to glassy synthetic polymers, is characterized to generate nonlinear adsorption. With a study of sorption and desorption for naphthalene by SOM, Gunasekara and Xing (2003) suggested that interaction of SOM with soil mineral surfaces may render the structural configuration of SOM to a more condensed state and result in highly nonlinear isotherms. HA aromatic moieties are suggested to be one important contributor to form the condensed state of HA, while HA aliphatic moieties is a contributor to form the expanded state (Salloum et al., 2002; Gunasekara and Xing, 2003; Kang and Xing, 2005). Hydrophobic interaction is responsible for partitioning and isotherm linearity. Additional interactions such as the possible π -bonds of aromatic molecules with aromatic moieties of SOM may be responsible for adsorption and the isotherm nonlinearity (Yang and Xing, 2009). Functional groups on aromatic rings will enhance the π -polarity/polarizability of aromatic rings and thus π -bonding interaction (Hickey and Passino-Reader, 1991). Therefore, interactions of SOM containing functional groups such as phenolic-OH with minerals could result in the π -polarity/polarizability enhancement of adsorbed SOM, and subsequently the adsorption affinity of adsorbed SOM would increase to show more nonlinear isotherms (Yang and Xing, 2009).

Nonlinear sorption would exhibit concentration-dependent organic carbon-normalized sorption coefficients (K_{oc}) , with higher K_{oc} values at low concentrations (Figure 9.13). Since the nonlinear sorption is a combination of linear partition and nonlinear adsorption, the influence of either SOM fractionation or conformation changes on nonlinear sorption may act on the linear partition component or the nonlinear adsorption component or both of them. It is clear that enhancement or reduction in K_{oc} is a constant in all range of the solute concentrations if variation of K_{oc} is originated from the changes of partitioning affinity because of the linear isotherm (Figure 9.13a). If K_{oc} variation comes from adsorption affinity changes, however, K_{oc} variation at low concentrations will be larger than that at high concentrations due to the nonlinear isotherm of adsorption (Figure 9.13b). Increase in adsorption and decrease in partitioning will cause the increase of relative contribution of adsorption to total sorption and isotherm nonlinearity.

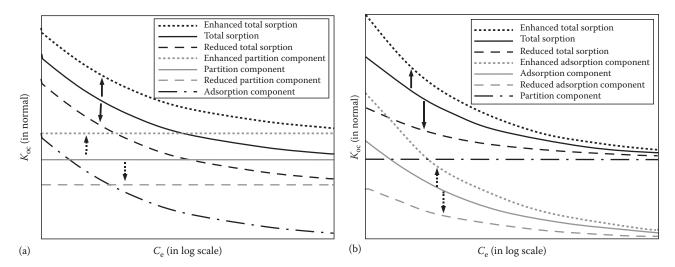

FIGURE 9.13 Enhancement or reduction of the concentration-dependent organic carbon-normalized sorption coefficients (K_{oc}) of total sorption derived from the enhancement or reduction of partition component (a) and adsorption component (b). K_{oc} of partition component was figured out based on the linear equation fitting of the isotherm of partition component, while that of adsorption component was obtained based on the Freundlich equation fitting of the isotherm of adsorption component.

9.2.5 Influence of Sorption and Desorption on Bioavailability of AOPs

The term bioavailability has been and is used in many different scientific fields, which consider interactions between a living cell and a chemical(s). There are many definitions of varying detail and complexity in the scientific literature, which can lead to confusion and inconsistency (Semple et al., 2007). However, the bioavailability should at least represents the "maximum quantity of a contaminant available for uptake by an organism within a given time period" (Semple et al., 2004). Both biological and chemical methods have been developed to assess organic compound bioavailability (Reid et al., 2000; Dean and Scott, 2004). In general, it is accepted that only the organic molecules dissolved in aqueous phase (i.e., water in soil) are bioavailable (Paterson et al., 1990; Scow and Hutson, 1992; White and Alexander, 1996; Cornelissen et al., 1998; Alkorta and Garbisu, 2001; Chiou et al., 2001; Gomez-Lahoz and Ortega-Calvo, 2005), whereas adsorbed molecules by soil solids cannot be bioavailable directly because they do not have direct contact with organisms and cannot be taken up. This non-bioavailability is valid whether the sorbent is a natural sorbent such as soil particle (Ehlers and Loibner, 2006) or an artificial sorbent such as activated carbon (Aktas and Cecen, 2007). Therefore, sorption and desorption process of AOPs in the soil-water systems can largely affect the bioavailability of the pollutants in soils.

Sorption of an organic compound by soil can decrease its biodegradation because only dissolved organic molecules in water can be bioavailable. On the one hand, sorption decreases the concentrations of the organic compound in aqueous phase (i.e., maximum quantity of a contaminant available for uptake), and consequently decreases the concentration-dependent uptake and degradation rate. Due to the observed hysteresis

(i.e., the difference between sorption and desorption processes) (Pignatello and Xing, 1996; Doucette, 2003), on the other hand, a significant amount of soil adsorbed organic molecules cannot be desorbed and thus is unavailable for microbe uptake and degradation, and also slow kinetics of this desorption process suggests that the desorbed rate of the organic compound from soil to water may fail to match the uptake and degradation rate and thus decrease biodegradation (McLeod and Semple, 2000). The sorption of an organic compound from water to soil solid matter is usually directly proportional to its $K_{\rm ow}$ (Schwarzenbach et al., 2003). Therefore high $K_{\rm ow}$ values indicate limited bioavailability and biodegradation of an organic compound in soil (Cerniglia, 1992; Reid et al., 2000; Semple et al., 2001, 2003).

Among the soil components, SOM is widely accepted to play a predominant role in sorption of AOPs. Consequently, SOM is also the main component that is responsible for the decrease of AOP bioavailability in the soil environment. Furthermore, SOM property that may affect AOP sorption, such as polarity, physical states (e.g., glassy and rubbery state) and aromaticity, could thus be expected to influence the AOP bioavailability. For example, functionalities and surface domain distribution of SOM may have joint effects on the bioavailability of phenanthrene, showing phenanthrene was mainly sequestrated in aromatic domains of lignin (Yang et al., 2010). Adsorbed SOM on minerals, forming a more condensed state than the bulk SOM and having stronger nonlinear sorption for AOPs (Gunasekara and Xing, 2003), may decrease the AOP bioavailability. The small amount of carbonaceous material (such as charcoal or soot) in soils in addition to SOM, exhibits a greater nonlinear adsorption of AOPs (Chiou, 1995; Gustafson et al., 1997; Chiou and Kile, 1998; Cornelissen et al., 2005) and may also decrease the AOP bioavailability (Xia et al., 2010). Therefore, biochars, derived from biomass, can be added as an environmental-friendly engineered sorbents to amend contaminated soils to promote pollutant sorption in soils and thus abate the transfer of AOPs from soil to water, plants, and soil microorganisms (Wang et al., 2010).

Nonlinear sorption of a given organic pollutant by soils and SOM can be reduced by the addition of other organic pollutants because of the competition and displacement, and thus enhance the concentration of the pollutant in water (Xing et al., 1996, Xing and Pignetello, 1998; White and Pignatello, 1999). Therefore, the bioavailability of a given organic pollutant can be enhanced by the addition of competitors (White and Pignatello, 1999). Addition of dissolved organic chemicals (e.g., organic acids, surfactants, and DOM) may not only pose the competition and displacement on the adsorbed pollutants but also enhance the solubility of AOPs in water to give the higher bioavailability (Xing and Pignetello, 1998; Voparil et al., 2003). For example, in field experiments, some surfactants at certain concentrations have been observed to enhance the uptake and accumulation of p,p'-DDE by specific Cucurbita pepo (zucchini) (White et al., 2006, 2007). Increasing temperature may also enhance the bioavailability of AOPs because the high temperature can promote desorption of sorbed organic chemicals from soil to water. Furthermore, addition of some chelating agents such as citrate, oxalate, or pyrophosphate was found to enhance desorption of hydrophobic compounds such as PAHs from SOM by solubilizing metal ions that are essential for cross-linking humic substances or bridging humic substances to mineral surfaces (Yang et al., 2001; Submmaniam et al., 2004). For example, exudation of chelating agents by plant roots was suggested to be responsible for the observed increased uptake of chlorinated hydrocarbon insecticides (White et al., 2003).

9.3 Uptake and Degradation by Plant and Soil Microbes

When an organic chemical enters into an organism (e.g., soil microorganism and plant) by uptake, it can be accumulated and degraded in the organism. Biodegradation (or to metabolize) is the most important process for the "ultimate" removal of AOPs in the environment, which can be defined as the process by which organic chemicals are decomposed by organisms and/or their extracellular enzymes into simpler substances (United Nations, 1997). In the biodegradation process by microorganism, organic compounds are used as carbon and electron source. Mineralization is the "ultimate" biodegradation and means conversion of organic compounds to inorganics in organism. Biotransformation is another biodegradation that means conversion of organic compounds into other organic compound(s). Unlike in mineralization, the products of biotransformation can be even more harmful than the parent compounds (Alexander, 1999). The products of biotransformation and the un-degraded chemicals may accumulate in organism and then be released into the environment or transferred into other organisms via food chains.

For biodegradation to occur, two prerequisites must be reached: (1) the compound must be bioavailable, that is, accessible to the target organism; and (2) the compound must be inherently biodegradable. The AOP accessibility is responsible for the physical contact of organic molecule with organism, which is needed before it is degraded by the organism or its extracellular enzymes (Rosenberg et al., 1992). The entering of organic molecule into organism by the uptake process is to attain this contact, and thus determines the compound available for the degrading organism (Reid et al., 2000; Semple et al., 2003). The accessibility of an organic molecule to a biological entity, that is, bioavailability, is of great importance because it is one of the key factors affecting contaminant biodegradation in soils (Mihelcic et al., 1993; Reid et al., 2000; Semple et al., 2003). This bioavailability is also important for the assessment of toxicity and ecological risk of an organic compound in soil. However, bioavailability alone is not enough to account for the possible degradation of AOPs. Other factors affecting the growth of organisms are also required for biodegradation. Moreover, bioavailability is not only organism dependent but also species dependent (i.e., bioavailability can be organism and species specific) (Guerin and Boyd, 1992; Kelsey et al., 1997; White et al., 1997). For example, both White et al. (1997) and Kelsey et al. (1997) noted that the extent of earthworm (Eisenia foetida) bioaccumulation and bacterial (Pseudomonas sp.) mineralization of soil-associated phenanthrene differed, although both organisms indicated a decline in bioavailability with increasing soil-pollutant contact time.

The organic molecules dissolved in aqueous phase (i.e., water in soil) are bioavailable because they have direct *contact* with organisms (Paterson et al., 1990; Scow and Hutson, 1992; White and Alexander, 1996; Cornelissen et al., 1998; Alkorta and Garbisu, 2001; Chiou et al., 2001; Gomez-Lahoz and Ortega-Calvo, 2005), whereas sorbed molecules by soil solids cannot be bioavailable and for uptake directly because they have not direct *contact* with organisms. The soil water dissolved molecules may also be poorly or not bioavailable if the molecule is dissolved in non-advecting water. Such water is hygroscopic or pellicular or water located in a soil pore with a neck pore diameter smaller than $0.3\,\mu\text{m}$ (Standing and Killham, 2007). Organisms such as soil microbes can occupy only a small fraction of the soil surface area.

The uptake of a chemical molecule by an organism occurs after that molecule has passed from the aqueous phase through a biological membrane (e.g., cell membrane) and into the interior of the organism. This uptake for most AOPs is believed to be passive, that is, it occurs by diffusion through the membrane rather than by active transport processes (Pignatello, 2006). Although the uptake and degradation of AOPs by organisms are kinetic processes, an apparent equilibrium between the pollutant concentrations in organisms and water, is commonly considered to reach after a long time contact of pollutants with organisms in the natural systems. Bioconcentration factor, a term, which is given by the ratio of the pollutant concentration in organisms to that in water, has widely been used to describe this apparent equilibrium.

Microorganisms and plants, in soil systems, are the most important organisms for degradation of AOPs. Therefore, the uptake and degradation of AOPs by soil microorganisms and plant do have important effects on the AOP fate in the environment. How and the extent of AOPs to be taken up and degraded by soil microorganisms and plant have been examined in the past.

9.3.1 Uptake and Degradation by Soil Microorganisms

Degrading microorganisms are ubiquitously distributed in the natural environment, such as in soils (bacteria and nonligninolytic fungi) and woody materials (ligninolytic fungi) (Alexander, 1999; Leung et al., 2007; Roesch et al., 2007). Microbes have developed enzymatic systems for the degradation of compounds emanating from natural processes (Leung et al., 2007). The diversity of soil microbial communities is enormous. It has been proposed that soil may contain 109-1010 microbial cells cm⁻³ and an estimated number of 10⁴–10⁶ distinct genomes per gram of soil (Torsvik et al., 2002; Gans et al., 2005; Roesch et al., 2007). However, AOPs have been produced and discharged for only about 100 years. Most of these manmade compounds have a molecular structure never observed in the natural environment, that is, the molecular structures are different from natural chemicals. Therefore, they are foreign and unfamiliar to the microbes and the degrader enzymes, implying the possible low biodegradation. AOPs may be biodegraded when (1) they are compatible with the catabolic enzymatic apparatus of a degrader microbe (Alexander, 1999; Leung et al., 2007), (2) the enzymatic apparatus of a microbe has a wide specificity (Hesselsoe et al., 2005; Baldrian, 2006), and (3) genetic adaptation occurs in a microbe leading to a new catabolic pathway for the pollutants (Janssen et al., 2005). The population of soil microbes, capable of degrading the organic contaminants, is a key for AOP degradation and has received a substantial amount of research (El Fantroussi and Agathos, 2005).

A wide variety of microorganisms including bacteria, fungi, and algae have successfully been cultured to remove the AOPs (especially for the readily biodegraded compounds) in discharged wastewater via anaerobic, aerobic, and sequential anaerobic–aerobic treatment processes called as activated sludge systems. However, conventional activated sludge systems often fail to achieve high efficiency in removal of POPs such as pesticides from wastewater due to the low biodegradability and high toxicity or the inhibition of the compounds to microorganisms. For those un-biodegraded AOPs, microorganisms in conventional activated sludge systems may act as a biosorbent and can remove the AOPs from wastewater by biosorption (Aksu, 2005). The mechanisms of AOPs uptake and degradation by microorganisms in soils could be similar to that as observed in wastewater.

Soil microbes are attached on the surfaces of soil particles in microcolony- or biofilm-like structures (Standing and Killham, 2007; Van Elsas et al., 2007). Dissolved organic molecules to

these sites with movement of water fluid promote contacts with degrading microbes. Therefore inherently biodegradable and water soluble AOPs are usually expected to be bioavailable and not persistent in soil if other conditions favor biodegradation (Semple et al., 2003). However, the uptake and degradation of AOPs by microorganisms occurs only after AOP molecule has passed from the aqueous phase through the cell membrane (a phospholipid bilayer) by a passive diffusion and into the interior of the microorganism (Schwarzenbach et al., 2003). This passive diffusion was accepted to be a partitioning process of AOPs between the biomembrane and water (Gobas et al., 1988; Dulfer and Govers, 1995; Escher and Schwarzenbach, 1996; van Wezel et al., 1996; Vaes et al., 1997; Schwarzenbach et al., 2003). This partitioning process is described by the membrane-water partition coefficients (K_{mw}) , which is given by the ratio of the pollutant concentration in membrane to that in water. Because chemical partitioning in real biomembranes is experimentally difficult, the artificial bilayer phospholipid vesicles, based on phosphatidylcholine monomers known as liposome, are widely accepted in the experiments as models of biomembrane. A linear relationship occurs between the liposome-water partition coefficients (K_{mw}) and the octanol-water partition coefficients (K_{ow}) (Gobas et al., 1988; Escher and Schwarzenbach, 1996; van Wezel et al., 1996; Vaes et al., 1997):

$$\log K_{\text{mw}} = a \log K_{\text{ow}} + b \tag{9.14}$$

where a and b are regression coefficients. From this equation, an HOC with a high octanol-water coefficient indicates favored partition from water to biological membranes. However, the range where this equation can be applied is limited. First, the slope of this linear relationship for PCB partitioning into liposome seems to decline, and even becomes negative when the chemical $\log K_{ow}$ above about 7 (Dulfer and Govers, 1995). Moreover, an HOC to partition into real cellular membranes is most preferred when its log K_{ow} is 1.5–4.0, as reviewed by Sikkema et al. (1995) and Ramos et al. (2002). This is because the multiphase nature of water-membrane lipid bilayers differs from water-octanol two-phase system. The water-lipid bilayer system has a hydrophilic interfacial phase, which creates surface tension between water and lipid "bulk" phases to prohibit the transfer of highly hydrophobic organic chemicals (log $K_{ow} > 4.0$) from water to lipid, whereas the water-octanol system has water and "bulk" (octanol) phases only (De Young and Dill, 1988). In the soil systems, the uptake of AOPs by microorganisms may be decreased by their sorption on soils because the sorption decreases the aqueous concentrations of AOPs. A ratio of K_{mw} to K_{oc} , for a given AOP, can be employed to describe its uptake availability by microorganisms from soils.

AOPs in contaminated soils can be degraded by degrading bacteria or fungi via an aerobic or anaerobic metabolism or both. In the aerobic metabolism process, molecular oxygen is incorporated into the aromatic ring prior to the dehydrogenation and subsequent aromatic ring cleavage. In the anaerobic metabolism process where molecular oxygen is absent, however,

alternative electron acceptors such as nitrate, ferrous iron, and sulfate are necessary to oxidize aromatic compounds. The basis of these mechanisms is the oxidation of the aromatic ring, followed by the systematic breakdown of the compound to PAH metabolites and/or carbon dioxide. The mechanisms of anaerobic metabolism of aromatic AOPs are still tentative and thought to occur via the hydrogenation of the aromatic ring (Bamforth and Singleton, 2005).

In the aerobic metabolism of AOPs by bacteria or fungi, there are three fundamentally different mechanisms, described in Figure 9.14 with PAHs as the initial degraded compounds (Bamforth and Singleton, 2005). The principal mechanism for the aerobic bacterial metabolism is the initial oxidation of the aromatic ring by the action of dioxygenase enzymes to form cis-dihydrodiols, followed by dehydrogenation to form dihydroxylated intermediates and then be further metabolized via catechols to carbon dioxide and water (Bamforth and Singleton, 2005). There are two main types of fungal metabolism by the non-ligninolytic and ligninolytic fungi, respectively (Bamforth and Singleton, 2005). The first step in the metabolism by nonligninolytic fungi, the majority of fungi in soils, is to oxidize the aromatic ring in a cytochrome P450 monoxygenase enzyme catalyzed reaction to produce an arene oxide (Sutherland et al., 1995) and subsequently hydrated via an epoxide-hydrolase catalyzed reaction to form a trans-dihydrodiol (Jerina, 1983). In comparison to the oxidation in aerobic bacterial metabolism, the monoxygenase enzyme here incorporates only one oxygen atom onto the ring to form an arene oxide and the sequent *trans*-dihydrodiol. Ligninolytic fungi under ligninolytic conditions can produce ligninolytic enzymes, which generates hydroxyl free radicals by the donation of one electron to oxidize AOPs (Sutherland et al., 1995). This oxidation is a nonspecific radical based reaction and generates quinine-like and acid-like structures rather than dihydrodiols (Sutherland et al., 1995). Because the hydroxyl free radical based reaction has low substrate specificity, ligninolytic enzymes are therefore able to degrade even the most recalcitrant compounds. Moreover, ligninolytic enzymes are secreted extracellularly (Kirk and Farrell, 1987), and thus theoretically able to diffuse into the soil matrix and potentially oxidize the soil adsorbed AOPs.

Besides the bioavailability of AOPs and microbial populations, it is apparent that environmental factors, inhibiting the growth of the pollutant-degrading microorganisms or altering the bioavailability of AOPs, could affect biodegradation. These factors mainly include contaminant toxicity, soil moisture, soil temperature, soil pH, and nutrient availability. Toxicity of an organic contaminant can limit biodegradation if the toxic effect of the compound is high enough to limit the microbe's degrading activity (Alexander, 1999). Organic compounds with a log $K_{\rm ow}$ between 1.5 and 4.0 are extremely toxic for microorganisms and other living cells because they partition preferentially in the cytoplasmic membrane, disorganizing its structure and

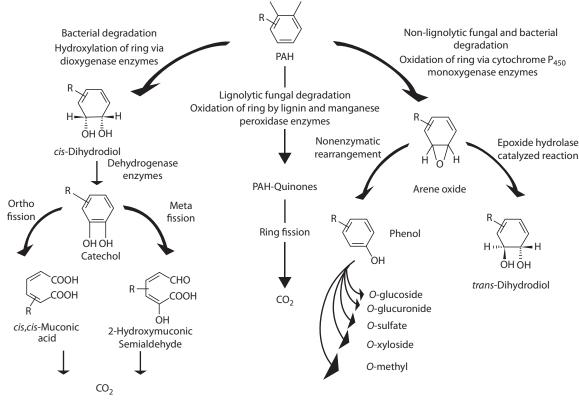

FIGURE 9.14 Three main pathways for PAH degradation by fungi and bacteria. (Bamforth, S.M., and I. Singleton. 2005. Bioremediation of polycyclic aromatic hydrocarbons: Current knowledge and future directions. J. Chem. Technol. Biotechnol. 80:723–736. Copyright Wiley-VCH Verlag GmbH & Co. KGaA. Reprinted with permission.)

impairing vital functions (Sikkema et al., 1995; Ramos et al., 2002). Soil moisture affects not only the supply of water and nutrients for microbes but also the transport of gases such as oxygen and other electron acceptors such as NO₃⁻ for bio-oxidation. Moreover, total water content of soil affects the bioavailable amount of an organic compound, for example, an increase in the total water content of soil leads to an increased desorption of an organic compound from the soil particles and the increased total amount of the organic compound in water where they are bioavailable (White and Alexander, 1996). Temperature can affect the biodegradation because (1) there are a minimum and a maximum temperature, typically within a range of 20°C-30°C, allowing growth for microbes, outside this range, temperatures make the microbes inactive; (2) Biodegradation of an organic compound in soil is a chemical reaction catalyzed by enzymes in soil, which is affected by temperature; and (3) water solubility and diffusivity of a HOCs are increased with increasing temperature (Nedwell, 1999; Igbal et al., 2007). Relative to AOPs in temperate soils, therefore, AOPs in tropical soils could be degraded more and faster because tropical soils are under very humid climates with higher temperature allowing desorption and dissolution of AOPs and active growth of microbes, while AOPs in cold soils could be degraded less and slower because cold soils are with lower temperature that makes the desorption and dissolution of AOPs less and the microbes inactive. Inorganic nutrients, as well as organic carbon sources, must be available for the growth of microbes. Large utilization of organic contaminants, as organic carbon sources in the microbial growth process, leads to the depletion of available inorganic nutrients and consequently inhibits the growth of microbes (Morgan and Watkinson, 1989).

9.3.2 Uptake and Degradation by Plant

The pollution of soils by AOPs such as pesticides leads to the subsequent pollution of plants/crops grown in these contaminated soils. Research in contamination of plants by organic compounds began as early as the 1950s, soon after many organochlorine insecticides were introduced for agricultural purposes (Lichtenstein, 1959). The levels of pesticide residues and other organic chemicals in plants accumulated from contaminated soils have since been largely reported (Chiou, 2002). Many soil-incorporated pesticides are now known to translocate into plants following their applications. Contaminated plants especially for the agricultural crops by toxic AOPs may cause the transfer of these AOPs to animals and human beings via food chains, and pose serious health risks. Plant uptake and storage are also a potentially key component in the global cycling of persistent organic pollutants (Dallavalle et al., 2004; Scheringer et al., 2004). Knowledge of contaminant uptake by plants is of vital interest not only because it will improve our understanding and alleviation of the crop-contamination problem but also because it may provide us with a means to effectively remediate contaminated soils by appropriate plantings (Chiou, 2002).

Plants can affect the fates of AOPs in soil through (Figure 9.15): (1) stabilizing and degrading the pollutants in the rhizosphere,

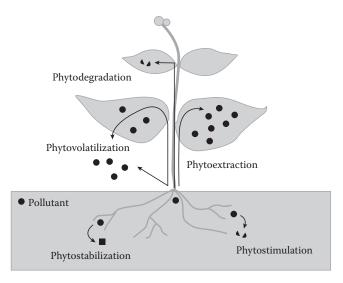

FIGURE 9.15 Possible fates of pollutants during phytoremediation: the pollutant (represented by black circles) can be stabilized or degraded in the rhizosphere, sequestered or degraded inside the plant tissue, or volatilized. (Reprinted from Pilon-Smits, E. 2005. Phytoremediation. Annu. Rev. Plant Biol. 56:15–39. With permission of Annual Reviews.)

(2) taking up the pollutants to plant issues, and (3) subsequent transporting, accumulating, degrading the pollutants in plant issues, or (4) volatilizing the pollutants to the atmosphere. These processes are generally named as phytostabilization, phytodegradation, phytoextraction, phytovolatilization, and phytostimulation (Pilon-Smits, 2005). Phytostabilization is a process that plants stabilize pollutants in soil either simply by preventing erosion, leaching, and/or runoff, or by converting pollutants to less bioavailable forms (Berti and Cunningham, 2000). Phytostimulation or rhizodegradation is a process that plants facilitate microbial degradation of organic pollutants by releasing simple organic molecules to promote the growth of degrading microbes in their rhizosphere (McCutcheon and Schnoor, 2003). Phytodegradation is a process that plants degrade organic pollutants directly through releasing degrading enzymes either inside the plant issues or into the soil (McCutcheon and Schnoor, 2003). Phytovolatilization is a process that certain pollutants taken up in plant tissues leave the plant in volatile form into the atmosphere (Pilon-Smits, 2005). Phytoextraction is a process that pollutants accumulate in plant tissues after uptake in plant tissues (Pilon-Smits, 2005). Phytodegradation and phytoextraction also represent transformation and subsequent accumulation of pollutants inside the plant issues. Uptake of the pollutants from soil and the subsequent transport of the pollutants inside the plant is a first step determining the degradation, transformation, accumulation, and volatilization of AOPs in plants.

9.3.2.1 Plant Uptake Pathways

The uptake of AOPs by plants mainly occurs via two pathways (Collins et al., 2006). One is the soil-water-plant pathway, in this pathway, AOPs translocate into plants by root uptake from soil solution and then transport possibly in the transpiration steam within the xylem (Figure 9.16). The other one is

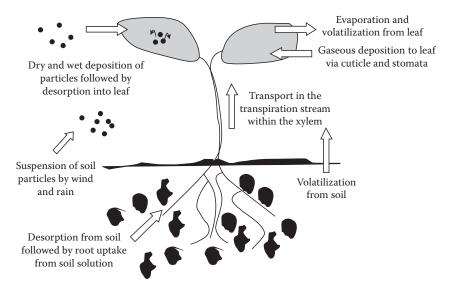

FIGURE 9.16 Principal pathways for the uptake of organic chemicals by plants. (Reprinted with permission from Collins, C., M. Fryer, and A. Grosso. 2006. Plant uptake of non-ionic organic chemicals. Environ. Sci. Technol. 40:45–52. Copyright 2006 American Chemical Society.)

the soil-air-plant pathway, in which AOPs translocate into plants by leaf uptake from the suspended soil particles or the gaseous AOPs volatilized from soil with a deposition process (Figure 9.16). After the uptake process, other plant processes involved in translocation, sequestration, and degradation of AOPs in plants may occur subsequently (Pilon-Smits, 2005). Some key parameters affecting the transport process of contaminants from soil to plant (the soil-to-plant transport process of contaminants) include the levels of contaminants in soil (or water), the contaminant physicochemical properties, the particular plant species, the soil types that sustains the plant, and the time of plant exposure (Chiou, 2002). Although leaf uptake may be important for volatile or semi-volatile organic compounds, only a very small fraction of the gaseous or the suspended soil particle bound-AOPs in atmosphere from contaminated soil can be translocated into plants by leaf uptake because plants can only use a small scale ambient air around their leaves while the AOPs in atmosphere from contaminated soil are mostly dispersed with wind and diluted in the air in a large scale. Therefore, the soil-water pathway through root uptake is considered as the main pathway for most AOPs from soil to plants (Chiou et al., 2001; Chiou, 2002; Pilon-Smits, 2005). In the following section, we also focus on the soil-water pathway through root uptake only.

9.3.2.2 Root Uptake and Translocation

Soil—water—plant pathway consists of two components: the uptake of AOPs from soil solution into plant roots and the transport of AOPs from the root to the shoot. Chemicals, before they can be transported upward to plant shoot via the xylem, must be moved from soil solution to the plant root constituents first and then moved to reach the xylem by penetrating a number of layers including the epidermis, cortex, endodermis, and pericycle (Figure 9.17), where one cell membrane (which is

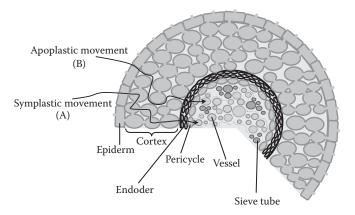

FIGURE 9.17 An illustrative diagram of translocation pathways of organic contaminant molecules with water among plant cells showing both apoplastic (A) and symplastic (B) pathways.

rich in lipids) at least exist to be penetrated at the endodermis (Collins et al., 2006). It is suggested that the solubility of AOPs in water (solution) and in the cell membrane determines their movement into roots and subsequent transport to the plant shoot (McFarlane, 1995).

AOPs can be taken up by plant roots via a passive and/or an active process from soil water, depending on the contaminant and plant types (Shone and Wood, 1974; Briggs et al., 1982). The uptake of most AOPs by plant roots has been shown to be the passive diffusive process, while a few hormone-like chemicals such as the phenoxy acid herbicides may be taken up by the active process (Bromilow and Chamberlain, 1995). The passive plant uptake process of contaminants by plant roots is derived by the water potential gradient created throughout the evapotranspiration within the xylem (Simonich and Hites, 1995; Paraiba, 2007). The passive root uptake process consists of two components (Briggs et al., 1983; Collins et al., 2006): (1) "equilibration"

of the aqueous phase in the plant root with the concentration in the surrounding soil solution and (2) "sorption" of the chemical onto lipophilic root solids. Lipophilic root solids include lipids in membranes and cell walls (Paterson et al., 1991). This root uptake of AOPs may be treated as a series of partitions from soil solution to plant water and then to plant organic constituents (Ryan et al., 1988; Chiou et al., 2001), where the partition into lipids is largely responsible for root concentration of relatively water-insoluble compounds.

Movement of water and AOPs across the root epidermis and cortex is the first step for the root uptake. There are two pathways through which AOPs can move across the root epidermis and cortex from soil water (Figure 9.17): one is the apoplastic through which AOPs and water movement involves diffusion between cell walls, not entry into the cells; the other one is the symplastic pathway through which AOPs and water movement is through the cell cytoplasm or vacuoles and to interconnected cells via the plasmodesmata (Wild et al., 2005). Initially, AOPs bound to the epidermis along the zone of elongation, passing through the epidermal cells to reach the cortex within the root hair, and branching zones of the root. The AOPs enter the epidermis radially; however, once within the cortex cells this movement is dominated by slow lateral movement toward the shoot. The lateral movement of AOPs toward the shoot within the cortex cells is dominated by movement within the cell walls, suggesting apoplastic flow through multiple cell walls, but with a low level of symplastic movement to transport compound into the cellular vacuoles (Wild et al., 2005).

Significant accumulation of AOPs including PAHs, chlorobenzenes, PCBs, and PCDD/Fs have been found in plant roots (DuarteDavidson and Jones, 1996). Lipophilic organic chemicals are observed to possess a greater tendency to partition into plant root lipids than hydrophilic chemicals. Briggs et al. (1983) established a linear relationship between the octanol-water partition coefficients (K_{ow}) of nonionized chemicals and the observed root concentration factor (RCF = chemical concentration in the root/concentration in external solution) for the uptake of O-methylcarbamoyloximes and substituted phenylureas by barley plants. For the uptake of organic chemicals by hybrid poplar trees, this relationship was also observed by Burken and Schnoor (1998). It was thus suggested that organic chemicals with log $K_{ow} > 3.0$ (Briggs et al., 1983) or log $K_{ow} > 4$ (Wild and Jones, 1992a; Burken and Schnoor, 1998) have a high potential for retention in plant roots. In addition to the hydrophobic nature of AOPs, their root uptake is also suggested to depend on the lipid content of the plant roots because root lipid is the place for storage of AOPs (Bromilow and Chamberlain, 1995; Schwab et al., 1998; Chiou et al., 2001). A linear relationship between the RCF of PAHs and the lipid content of 12 plants was observed by Gao and Zhu (2004). The important influence of root lipid content for the root uptake behavior has been also illustrated by the higher retention of organic compounds in the peels of carrot and potato compared to their pulp (Wild and Jones, 1992b; Fismes et al., 2002).

The AOPs taken into the plant roots can be transported upward as dissolved species with water from the plant roots into other parts through evapotranspiration within the xylem. However, chemicals, before they can be transported upward to plant shoot via the xylem, must dissolve in plant solution from the root membrane/lipids. This process can be treated as a series of partitions from plant organic constituents to plant solution (McFarlane, 1995). Due to this partition behavior, lipophilic organic chemicals are expected to possess a lower tendency to dissolve into plant solution from root lipids than hydrophilic chemicals and subsequent lower transport upward to shoot.

The transpiration stream concentration factor (TSCF = concentration in xylem/concentration in external solution) was developed to describe the total uptake of AOPs in the plant shoot from soil solution by Briggs et al. (1982). A relationship between TSCF and the K_{ow} of AOPs was derived (Figure 9.18), showing a maximum of TSCF for chemicals with log $K_{ow} = 1.8$ (Briggs et al., 1982). Similar relationships (Figure 9.18) were observed by Burken and Schnoor (1998) and Hsu et al. (1990). A possible explanation for the K_{ow} optima is that hydrophilic chemicals have lower partition into the lipids of cell membrane/walls and thus less get into the plant root, while lipophilic chemicals get stuck in the lipids of cell membranes/walls and cannot enter the cell fluids for the later translocation in the transpiration stream (Bromilow and Chamberlain, 1995). However, organic chemicals with moderate hydrophobicity are hydrophobic enough to move through the lipid bilayer of membranes, and still water soluble enough to travel out into the cell fluids.

It should also be noted that other non-lipid plant components such as waxes, lignin, and suberin may absorb organic chemicals (Rutherford et al., 1992; Mackay and Gschwend, 2000; Chen et al., 2004, 2005; Wang et al., 2007). Therefore, lipid alone may not be enough to interpret the plant uptake of AOPs and thus underestimate their potential accumulation.

9.3.2.3 Models for the Plant Uptake by Root

At the present, there are a lot of nonequilibrium models (Riederer, 1990; Trapp et al., 1990; Paterson et al., 1994; Trapp and Matthies, 1995; Tam et al., 1996), formulated on a differential mass-balance due to the rates of contaminant interface transfer, plant growth and transpiration, and contaminant metabolism, along with some estimated transfer coefficients, and equilibrium models (Briggs et al., 1982; Trapp, 1995), assuming an apparent equilibrium between AOP concentrations in plants and water after plant exposure to chemicals over a certain period of time, these models are developed to assess the plant uptake of contaminants from soil and water and to relate the plant contaminant levels to physicochemical properties of the contaminants as well as to the properties and compositions of plants and soils. However, the applications of equilibrium models are limited because the actual state of a contaminant in plants may or may not be at equilibrium. Although nonequilibrium models delineated the uptake rates of contaminants with time, the model calculations are very sensitive to the accuracy of assumed contaminant interface-transfer rates and coefficients. Recently, a quasi-equilibrium partition-limited model, accounting for the passive plant uptake of contaminants from soil or water, has been developed by Chiou et al. (2001) and later demonstrated as an effective model in predicting the plant uptake (Zhu and Gao, 2004; Li et al., 2005; Yang and Zhu, 2007; Zhang and Zhu, 2009). The partition-limited model takes explicit account of the plant contaminant level in relation to the source level and plant composition. Moreover, the model contains both equilibrium and kinetic features and sets the upper (equilibrium) limit for the level of a contaminant in a plant with the respective contaminant level in solution. Therefore, the actual equilibrium between the contaminant in the plant and in the solution at a given time can be estimated (Chiou, 2002). The partition-limited model, for plant uptake of AOPs from a soil-free solution, equates the concentration of a contaminant either in the whole plant or in a specific part of the plant (α_{nt}) , expressed as the mass of contaminant per unit wet mass of the plant, with the contaminant concentration in external water (C_w) at the time of sample analyses (Chiou et al., 2001)

$$C_{\rm pt} = \alpha_{\rm pt} C_{\rm w} [f_{\rm pom} K_{\rm pom} + f_{\rm pw}]$$
 (9.15)

where

 K_{pom} is the contaminant partition coefficient between plant organic matter and water

 $f_{\rm pom}$ is the total weight fraction of the organic matter in the plant

 $f_{\rm pw}$ is the weight fraction of water in the plant, either for the whole plant or for a specific part of it

The term α_{pt} (\leq 1), called the *quasi-equilibrium factor*, expresses the extent of approach to equilibrium of any absorbed contaminant in the plant (or in a part of it) with respect to the same contaminant in the external water phase. In this model, α_{pt} is

a time-dependent parameter and may be viewed as the ratio of the respective concentrations in plant water and external water at the time of sample analyses. Thus, $\alpha_{\rm pt}=1$ denotes the attainment of equilibrium. For plants in contaminated soils, the contaminant concentration in external water $(C_{\rm w})$ is related to the contaminant concentrations in SOM $(C_{\rm som})$ and the contaminant partition coefficient between SOM and water $(K_{\rm som})$, $C_{\rm w}=C_{\rm som}/K_{\rm som}$, based on the assumption that SOM acts as a partition medium and is responsible for the total soil sorption of the contaminant (Chiou et al., 2001).

Because the organic matter in most root and leaf crops are polar carbohydrates, cellulose, and proteins, and nonpolar lipids, the $f_{\rm pom}K_{\rm pom}$ is simplified as the sum of the contributions by carbohydrates and lipids based on a further assumption that the partition coefficients of the compounds with the relatively polar carbohydrates, cellulose, and proteins are practically the same (Chiou et al., 2001)

$$C_{\rm pt} = \alpha_{\rm pt} C_{\rm w} [f_{\rm lip} K_{\rm lip} + f_{\rm ch} K_{\rm ch} + f_{\rm pw}]$$
 (9.16)

where

 f_{lip} and f_{ch} are total weight fraction of the lipids and carbohydrates in the plant, respectively

 K_{lip} and K_{ch} are the contaminant lipid–water partition coefficients and carbohydrate–water partition coefficients, respectively

The application of this partition-limited model requires values of the individual carbohydrate-water partition coefficients (K_{ch}) as well as the individual actual lipid-water partition coefficients (K_{lip}). However, these values are not available. Although octanol-water partition coefficients (K_{ow}) and assumed K_{ch} values (0.1–3 according to the corresponding K_{ow} values) were assumed to represent the actual K_{lip} and K_{ch} values, respectively, this treatment may result in the underestimation of actual K_{lip} and K_{ch} values and thus the deviation of the model predicted results from the experimental data (Zhang and Zhu, 2009). Especially for chemicals with large K_{ow} values, this underestimation on K_{lip} and K_{ch} values and the deviation of the model prediction are very significant (Barbour et al., 2005; Li et al., 2005). Carbohydrates are also important for plant uptake because of its predominant content in plant root though carbohydrates have lower partitioning affinity than lipids (Zhang and Zhu, 2009). The observed relationships of $K_{\rm lip}-K_{\rm ow}$ and $K_{\rm ch}-K_{\rm ow}$ may improve the prediction and help the application of the partition-limited model (Zhang and Zhu, 2009).

9.3.2.4 Degradation and Removal of the AOPs in the Plants

After uptake in plant issues and the subsequent transport, AOPs may accumulate in plant issues. AOPs in the plant may also be degraded or volatilized to atmosphere, thus reducing their concentration in the plant tissues. AOPs can be degraded in the process of plant metabolism via their own enzymatic activities.

This process has been reviewed by Burken (2003). The degradation process includes transformation reactions (e.g., oxidation), conjugation (e.g., with glutathione), and finally sequestration (e.g., into the cell wall). Degradation process and rates are specific to chemicals and plant species (Schnabel et al., 1997; Chekol et al., 2002; Hannink et al., 2002). Plant degradation has been observed for AOPs including herbicides, MTBE, trichloroethylene, benzene, pyrene, and the explosives (Huckelhoven et al., 1997; Ugrekhelidze et al., 1997; Hannink et al., 2002; Shang and Gordon, 2002; Burken, 2003; Winnike-McMillan et al., 2003; Nepovim et al., 2004).

The uptake and degradation of AOPs by plants suggest that plants can be employed in the remediation of contaminated soils by selection of favorable plant species. However, the soil properties, toxicity level, and climate should allow plant growth. Favorable plant properties for phytoremediation in general are to be fast growing, high biomass, competitive, hardy, and tolerant to pollution. Plants, having large and dense root systems and high levels of degrading enzymes would certainly favor the uptake and degradation of soil AOPs (Pilon-Smits, 2005). Moreover, this phytoremediation is limited by root depth because the plants have to be able to reach the pollutant. Root depth is typically 50 cm for herbaceous species or 3 m for trees, although certain phreatophytes that tap into groundwater have been reported to reach depths of 15 m or more, especially in arid climates (Negri et al., 2003).

9.3.3 Rhizosphere Processes of AOPs

The rhizosphere is an area that extends approximately 1 mm around the plant root (Pilon-Smits, 2005). In the rhizosphere zone, the pollutant can be stabilized or degraded by the plant roots, microbes and plant- and microbe-derived chemicals such as bio-surfactants and enzymes. AOPs can be stabilized in the rhizosphere soil by plants either simply through preventing erosion, leaching, and runoff, or through converting pollutants to less bioavailable forms (Berti and Cunningham, 2000). In the rhizosphere soil, microbial densities are 1-4 orders of magnitude higher than in bulk soil from the general rhizosphere effect (Salt et al., 1998), that is, plants release the photosynthesis-derived organic compounds in the rhizosphere for heterotrophic fungi and bacteria as carbon sources and thus promote the growth of microbes (Bowen and Rovira, 1991). In turn, rhizosphere microbes can promote plant health by stimulating root growth (some microorganisms produce plant growth regulators), enhancing water and mineral uptake, and inhibiting growth of other pathogenic soil microbes (Kapulnik, 1996).

The rhizosphere zone is the place for plant root uptake because plant roots can only take up water and the species dissolved in the water that they contact. It is also the important place for the uptake and degradation by soil microbes. Most of the soil physicochemical and biological interfacial processes that governing the fate of AOPs can be found in the rhizosphere zone. Moreover, these soil physicochemical and biological interfacial processes in the rhizosphere may be affected by various plant and/or microbial activities. For example, some bacteria can release biosurfactants (e.g., rhamnolipids) that make hydrophobic pollutants more water

soluble and subsequent enhance the bioavailability of these pollutants (Volkering et al., 1998). The observed AOPs that are degraded in the rhizosphere by microbial activity include PAHs, PCBs, and petroleum hydrocarbons (Hutchinson et al., 2003; Olson et al., 2003). Plant exudates or lysates may also enhance the pollutant water solubility and promote biosurfactant-producing microbial growth (Siciliano and Germida, 1998). Furthermore, plant- and microbe-derived enzymes can not only enhance the solubility of organic pollutants but also their degradation through oxidation and modification of side groups (Wolfe and Hoehamer, 2003).

There are two ways by which the degradation of AOPs in the rhizosphere can be promoted by plants: one is the direct oxidation by releasing enzymes and the other is phyto-stimulation of microbial degradation. Plants can stimulate the microbial degradation because (1) plants release carbon compounds into the rhizosphere to facilitate microbial growth and increase the microbial density, and (2) some released plant compounds may also induce specific microbial genes involved in the degradation or act as a cometabolite to facilitate microbial degradation (Fletcher and Hegde, 1995; Leigh et al., 2002; Olson et al., 2003). In general, 20% of carbon fixed by a plant is released into the rhizosphere from its roots (Olson et al., 2003).

Because of the possible enhancement of the uptake and degradation of AOPs by the complex plant-microbe interactions in the rhizosphere, these rhizosphere processes may be optimized in the remediation design to favor the removal of AOPs from the contaminated soil. This remediation taking place in the rhizosphere zone is called as rhizosphere remediation. In this remediation, optimized plant selection based on the rhizosphere processes is the most important step. Expected plants for rhizosphere remediation are those with highly effective uptake and degradation of AOPs, or those that can stimulate microbial degradation, or both of them. A large root surface area may favor phytostimulation, as it promotes microbial growth. Furthermore, production of specific exudate compounds may further promote rhizodegradation via specific plant-microbe interactions (Olson et al., 2003). The biomass, extent and dense of root systems, and the ability to increase the abundance and species degrading microbes should be considered in the selection of plants for rhizosphere remediation. If microbial consortia are responsible for the rhizosphere remediation process, it may be possible to increase the abundance of these species by adding them to the soil (a process called bioaugmentation). It is also possible to regulate the soil conditions such as soil water, nutrients and reducing/oxidizing conditions to provide an optimal environment for rhizosphere processes such as plant and microbial growth.

9.4 Effects of Surfactant on Soil Physicochemical and Biological Processes

Surface-active agents (surfactants), a class of manmade dissolved and/or colloidal organic matter widely used in household and industries as detergent formulations and surface cleaners with huge discharge quantities into the environment, are observed to alter HOC sorption and uptake process in the soil environment. For example, surfactants in water especially with their micelle formation have the ability to enhance the solubility of HOCs and then decrease their sorption by soils (Kile and Chiou, 1989; Edwards et al., 1991). This phenomenon is interpreted by the predominant role of chemical solubility in their physicochemical and biological processes including sorption by soils and uptake by plants and microbes. Therefore, surfactants could be used to remove HOCs from contaminated soils by enhancing chemical solubility (West and Harwell, 1992). However, the adsorbed surfactants on soil mineral surfaces exhibit high sorption of organic chemicals and consequently would attenuate mobility of HOCs (Boyd et al., 1988; Lee et al., 1989; Sheng et al., 1996). It is also observed that cell-associated bio-surfactants facilitate hydrocarbon uptake (Zajic and Seffens, 1984). Humic substances, the most important soil component controlling the physicochemical and biological processes of HOCs, are also surface-active compounds and their dissociated form could be likened to anionic surfactants (West and Harwell, 1992).

9.4.1 Surfactant

Surfactants are surface active because they favor to concentrate at interfacial regions such as air-water, oil-water, and solid-liquid interfaces. Their surface activity derives from their amphiphilic structure, that is, their molecules contain a polar ionic hydrophilic moiety (referred to as the head group) as well as a nonpolar hydrophobic moiety (the tail group). According to the charge nature carried by the hydrophilic portion (head group) of the molecule, surfactants are classified to four types including anionic (negatively charged), cationic (positively charged), nonionic (no charge), and zwitterionic (with both negative and positive charges) surfactants. Bacteria, yeasts, and fungi have the capability to synthesize surfactants, commonly referred to as biosurfactants (Zajic and Seffens, 1984).

A phenomenon unique to surfactants is the self-assembly of molecules into dynamic clusters called micelles above certain concentrations in water (Figure 9.19). The concentration of a surfactant to form micelles is characterized as critical micelle concentration (CMC). At concentrations below the CMC, the dissolved surfactant is all in monomeric form; above the CMC, the amount of surfactant in water is in excess of a critical amount of surfactant monomers and to form micelles. CMC is different for every surfactant, typically ranging between 0.1 and 10 mM (West and Harwell, 1992). In a micelle, the individual monomers are oriented with their hydrophilic moieties in contact with the aqueous phase and their hydrophobic moieties tucked into the interior of the aggregate (Figure 9.19). Another phenomenon of surfactants is that the surfactant chemical structure achieves a proper balance of hydrophilic and hydrophobic interactions at the interface to obtain large reductions in the interfacial tension (Bourrel and Schechter, 1988). Surfactants are sensitive to temperature (Rosen, 1989). For ionic surfactants, there is a temperature called Krafft point at which the solubility of the surfactant becomes equal to its CMC. At temperatures below this Krafft point, ionic surfactants exist as monomers without micelles formed. Micelles are formed at temperatures

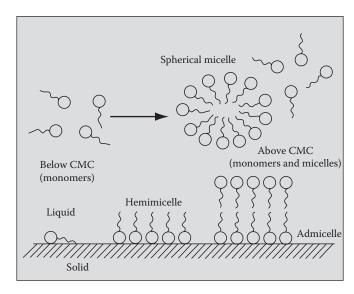

FIGURE 9.19 Examples of surfactant micellization. (Reprinted with permission from West, C.C., and J.H. Harwell. 1992. Surfactants and subsurface remediation. Environ. Sci. Technol. 26:2324–2330. Copyright 1992 American Chemical Society.)

higher than the Krafft point. For nonionic surfactants, there is also a critical temperature called the cloud point, at temperatures above which, the surfactant begins to form a separate surfactant-rich aqueous phase by coacervation and results in a high turbidity of the surfactant solution. Emulsifying organic chemical and oils in water is important for the application of surfactants. Hydrophilelipophile balance (HLB) scale, which was designed for matching surfactant structure to an organic chemical to be emulsified in water (Rosen, 1989), can be obtained commonly from the manufacturers. Each surfactant has an HLB number indicating the water soluble of the surfactant and the types of organic chemicals it can emulsify. The surfactant with higher HLB number exhibits more water soluble. The surfactant HLB requirement of organic chemicals for their emulsification in the surfactant solution is directly related to their hydrophobicity. Generally, as the K_{ow} of organic chemicals increases (water solubility decreases), the HLB requirement decreases. Concentrating of surfactants at solid-liquid interfaces is commonly exhibited by sorption on solid surface. At very low concentrations, adsorbed surfactant monomers on solid surfaces begin to aggregate and form micelle-like structures called admicelles or hemi-micelles, depending on whether the aggregates have one or two surfactant layers (Figure 9.19). The tendency of surfactant to form admicelles or hemi-micelles is dependent on interactions between the hydrophilic moiety of the surfactant and the solid surface (West and Harwell, 1992).

9.4.2 Solubility Enhancement by Surfactant

Because of the predominant role of chemical solubility in their physicochemical and biological processes including sorption by soils and uptake by plants and microbes, these processes of HOCs could be promoted or attenuated by altering their solubilities. Surfactants could greatly promote the (apparent) water

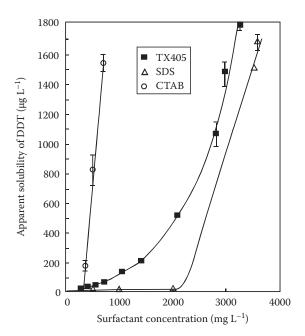

FIGURE 9.20 Water solubility enhanced of DDT by TX-405, SDS, and CTAB. (Reprinted with permission from Kile, D.E., and C.T. Chiou. 1989. Water solubility enhancement of DDT and trichlorobenzene by some surfactants below and above the critical micelle concentration. Environ. Sci. Technol. 23:832–838. Copyright 1989 American Chemical Society.)

solubility of relatively insoluble organic solutes (Figure 9.20) and then decrease their partition into an organic phase such as SOM because the surfactant micelle offers a relatively large microscopic nonpolar environment (i.e., the organic interior of micelles acts as an organic pseudophase) to allow for solute partition (Rosen, 1989). This phenomenon is called solubilization (Rosen, 1989). The increase in the solubility of a contaminant in a surfactant solution can be dramatic as shown in Figure 9.20. According to the dominant role of chemical solubility in their physicochemical and biological processes, solubilization of organic chemicals by surfactants, therefore, provide a potential means to remove contaminants from contaminated soils if the surfactant adsorbed on the soil does not strongly enhance the contaminant sorption (West and Harwell, 1992).

The solubility enhancement is related to surfactant monomer and micelle concentrations and the corresponding solute partition coefficients (Kile and Chiou, 1989), which can be described by a two-phase separation model using the following equation:

$$\frac{S_{\rm w}^{\star}}{S_{\rm w}} = 1 + K_{\rm mn} X_{\rm mn} + K_{\rm mc} X_{\rm mc} \tag{9.17}$$

where

 $S_{\rm w}^{\star}$ and $S_{\rm w}$ are the apparent water solubility of solute in surfactant solution and solubility of solute in pure water, respectively

 $X_{
m mn}$ is the concentration of surfactant monomers in water $X_{
m mc}$ is the concentration of surfactant micelles in water

 $K_{\rm mn}$ is partition coefficients of a solute between surfactant monomers and water

 $K_{\rm mc}$ is solute partition coefficients between the aqueous micellar phase and water

All concentrations are expressed in moles per liter. At a given temperature, $S_{\rm w}$, $K_{\rm mn}$, and $K_{\rm mc}$ are constants. If the surfactant concentration X < CMC, then $X_{\rm mn} = X$; if X > CMC, $X_{\rm mn} = CMC$ and $X_{\rm mc} = X - CMC$. Kile and Chiou (1989) applied this equation successfully to analyze the apparent water solubilities of extremely water-insoluble DDT (Figure 9.20) and relatively soluble TCB in the presence of nonionic surfactants (Triton series and Brij 35), an anionic surfactant (sodium dodecyl sulfate [SDS]), and a cationic surfactant (cetyltrimethylammonium bromide [CTAB]).

An alternative method to quantify surfactant solubilizing performance in the ranges of surfactant concentrations above CMCs is to measure the molar solubilization ratio (MSR) (Edwards et al., 1991). MSR is defined as the number of moles of compound solubilized per number of moles of micellized surfactant, and can be calculated as follows:

$$MSR = \frac{S_{\rm w}^{\star} - S_{\rm cmc}}{C_{\rm s} - CMC} \tag{9.18}$$

where

 C_s is the surfactant concentration at which S_w^* is evaluated S_{cmc} is the compound apparent solubility at CMC

MSR may be obtained from the slope of solubilization curves in the ranges of surfactant concentrations above CMCs. Based on the molar volume of water (1.8 \times 10⁻² L mol⁻¹ at 25°C), $K_{\rm mc}$ can also be calculated from MSR (Zhu and Feng, 2003),

$$K_{\rm mc} = \frac{55.4 \times MSR}{S_{\rm cmc}(1 + MSR)}$$
 (9.19)

Observed solubility enhancements are related to the properties of organic compounds and surfactants (Kile and Chiou, 1989; Edwards et al., 1991; Diallo et al., 1994; Jafvert et al., 1994; Sun et al., 1995). Theoretical models have also been developed to estimate micellar partitioning coefficients (K_{mc} or MSR) using surfactant and solute specific properties, including surface tension, molecular surface area, solute's structural formula, and Henry's constant (Smith et al., 1987; Liu et al., 2000). In an aqueous system, the extent to which a solute will partition in a surfactant micelle (K_{mc} or MSR) can be related to the octanol-water partition coefficients (K_{ow}) of the solute (Kile and Chiou, 1989; Edwards et al., 1991; Jafvert and Heath, 1991). In general, a solute with the larger K_{ow} exhibits the greater solubilization with higher $K_{\rm mc}$ and MSR. For the nonionic surfactants, their enhancement and the estimated micellar partitioning coefficients of a given solute are closely in proportion to the nonpolar group content of the surfactant, provided that the micelle size is sufficiently large (Kile and Chiou, 1989). For surfactants that have the same nonpolar chain length, the solubilizing power for organic solutes by the inner nonpolar core of the surfactant micelle follows as nonionic > cationic > anionic surfactants (Tokiwa, 1968; Kile and Chiou, 1989). The efficacy of surfactant-enhanced solubility is also limited by the concentration and stability of surfactant micelles. For example, nonionic surfactants can partition into trapped residual phases if their solubilities in an organic solute called as nonaqueous phase liquids (NAPLs) are high (Zhao et al., 2006), whereas anionic surfactants are subject to losses by precipitation with ions (Yang et al., 2007).

Relationships between the surfactant structure and the solubilization extent have been reported for alkanes, monocyclic aromatic hydrocarbons, and substituted monocyclic aromatic hydrocarbons (Diallo et al., 1994; Saitoh et al., 1994). A two-state model described by Mukerjee (1979) considers the hydrophobic core of a micelle and the hydrophilic outer shell as two distinct environments for solubilization, and solutes may be solubilized in either region depending on their molecular properties such as polarity (Mukerjee, 1979; Rosen, 1989). For nonpolar compounds such as alkanes where solubilization takes place only in the core of micelles, relationships between the extent of solubilization and compound properties or the surfactant structure have been reported (Diallo et al., 1994). For monocyclic aromatic hydrocarbons and PAHs, solubilization in nonionic surfactant micelles may occur in the core as well as in the shell region of the micelles because these compounds are slightly polar due to the resonance of π -electrons in the aromatic ring (Ruelle et al. 1992; Graziano and Byungkook, 2001). However, the solubilization and micellewater equilibrium partition coefficients of the PAHs in various surfactant solutions, due to the resonance of π -electrons in the aromatic rings, increased with the volume and size of the polar shell region of the surfactant micelles rather than the size of the hydrophobic core of the micelle (Bernardez and Goshal, 2004).

Mixed surfactants such as the anionic-nonionic surfactant system exhibit synergistic solubilization for PAHs and NAPLs because the formation of mixed micelles to reduce their CMC and consequently prohibit the partition of nonionic surfactant to NAPLs and the precipitation of the anionic surfactant with ions (Zhu and Feng, 2003; Yang et al., 2005b, 2006; Zhao et al., 2006). When surfactants are combined with oils in certain ratios, they may form stable microscopic mixtures called microemulsions, which are stabilized through the interactions with water of the polar head groups of surfactants attached to the oil particles. Microemulsions are especially effective in enhancing the water solubility of nonpolar organic contaminants, due to solute solubilization into the resulting suspended microscopic oil-surfactant phase (Kile et al., 1990). In comparison with normal surfactants, microemulsions exhibit virtually no monomermicelle transitions (i.e., no CMCs) and hence possess a separate partition phase more effectively than normal surfactants at very low concentrations.

9.4.3 Effect of Surfactant on the Sorption by Soil

Surfactants have a tendency to concentrate (i.e., sorption) on solid surface at the solid-liquid interface and to aggregate and form micelle-like structures such as admicelles or hemimicelles on the surface at very low concentrations (West and Harwell, 1992). Similar to micelles in water, these micelle-like structures can also be expected to exhibit a partitioning ability for organic solutes and consequently result in the uptake of solutes onto or into the adsorbed surfactant phase. In a soil-water system, therefore, surfactant imposes two opposing effects on the sorption of AOPs: the sorbed surfactant increases contaminant sorption, whereas the unsorbed surfactant promotes contaminant dissolution in water (i.e., decreases contaminant sorption by solubilization). This simultaneous effect of soilsorbed and unsorbed surfactants on contaminant sorption and the consequent change in contaminant apparent sorption coefficient (K_d^*) in a soil-water mixture have been addressed and accounted by the following equation (Sun and Boyd, 1993; Chiou, 1998; Lee et al., 2000), given as

$$K_{\rm d}^{\star} = \frac{K_{\rm d} + f_{\rm sf} K_{\rm sf}}{1 + X_{\rm mn} K_{\rm mn} + X_{\rm mc} K_{\rm mc}}$$
(9.20)

or, in a more useful alternative form, as

$$\frac{K_{\rm d}^{\star}}{K_{\rm d}} = \frac{1 + f_{\rm sf} K_{\rm sf} / K_{\rm d}}{1 + X_{\rm mn} K_{\rm mn} + X_{\rm mc} K_{\rm mc}}$$
(9.21)

where

 $K_{\rm d}$ is as defined before

 $f_{\rm sf}$ the mass fraction of the sorbed surfactant in soil

 $K_{\rm sf}$ is the solute (contaminant) sorption coefficients between sorbed surfactant and water

The term $f_{\rm sf}$ is for the sum of adsorbed and partitioned surfactant. Here, $K_{\rm sf}$ is not a direct function of $f_{\rm sf}$, but rather, a function of the aggregation state of the sorbed surfactant molecules. In principle, only the adsorbed surfactant can form a molecular aggregation, the extent being related to the amount adsorbed and mineral surface properties (Gu et al., 1992; Rutland and Senden, 1993; Nayyar et al., 1994).

The magnitude of $(1 + X_{\rm mn}K_{\rm mn} + X_{\rm mc}K_{\rm mc})$ in Equation 9.21, describing the water solubility enhancement of solutes by surfactant, is determined by surfactant type and its concentration in water as well as by contaminant properties. According to the equation, if a surfactant is present, apparent sorption coefficients $(K_{\rm d}^*)$ of solutes by soil could be higher or smaller than $K_{\rm d}$, that is, the $(1 + f_{\rm sf}K_{\rm sf}/K_{\rm d})$ is higher or smaller than $(1 + X_{\rm mn}K_{\rm mn} + X_{\rm mc}K_{\rm mc})$, which depends on the amount of surfactant adsorbed on soil $(f_{\rm sf})$, the partitioning ability of adsorbed surfactant $(K_{\rm sf})$, the concentrations of surfactant in water $(X_{\rm mn}$ and $X_{\rm mc})$, and the partition ability of surfactant monomers $(K_{\rm mn})$ and micelles $(K_{\rm mc})$ in water. In the presence of a given surfactant,

 $K_{\rm d}^{\star} > K_{\rm d}$ indicates that the surfactant can be used for the purpose of retarding organic solutes in soil to prohibit their transfers, whereas $K_{\rm d}^{\star} < K_{\rm d}$ indicates that the surfactant may be applied in soil remediation to promote desorption of organic contaminants from soil. Surfactant-enhanced desorption and washing process are only effective when the equilibrium surfactant dose in water is greater than its CMC, because (1) most of surfactant molecules are sorbed onto soil below its CMC (Jafvert, 1991; Pennell et al., 1993; Edwards et al., 1994; Kommalapati et al., 1997; Chu and So, 2001; Zhu et al., 2003), (2) the partition ability of surfactant monomers ($K_{\rm mn}$) is very small for most surfactants (Sun and Boyd, 1993; Chiou, 1998; Lee et al., 2000), and (3) no micelle partition occurs below its CMC.

Cationic surfactants can be expected to adsorb significantly on soil mineral solids (which are generally negatively charged) because of the attractive coulombic interaction between the surfactant head group and the solid surface. The sorption of cationic surfactants on clays and soils that contain significant cation exchange sites is also known to take place primarily by a cation exchange process (Theng et al., 1967; Barrer, 1978; Lee et al., 1989; Xu and Boyd, 1994). Because of the possible incorporation of the significant adsorbed amount of cationic surfactants and the additional microscopic nonpolar phase for solute partition created by the adsorbed surfactant on soils (i.e., to give large $f_{\rm sf}K_{\rm sf}$), cationic surfactants makes $K_{\rm d}^{\star}\gg K_{\rm d}$ for nonpolar solutes (Boyd et al., 1988; Smith et al., 1990). Therefore, the addition of cationic surfactants to soil-water systems would normally increase (rather than decrease) the sorption of organic pollutants on soil and hence have been used to reduce pollutant migration through a soil profile and promote pollutant immobilization in soil (Boyd et al., 1988; Lee et al., 1989; Sheng et al., 1996).

In comparison with cationic surfactant, nonionic surfactants adsorb weakly on soil. Anionic surfactants also adsorb weakly on soil due to the repulsive coulombic interaction between its head group and the surfaces of soil minerals (Rouse and Sabatini, 1993). Therefore, both their weak adsorption on soil and high solubilization for AOPs make anionic and nonionic surfactants desirable for soil remediation. However, some nonionic surfactants may adsorb on soils with a significant amount and hence increase AOPs sorption, making them inappropriate for soil remediation (Zhu et al., 2003). In general, nonionic surfactants with higher water solubility show the lower tendency for their adsorption on mineral surfaces. Their adsorption depends on the contents of soil/sediment organic matter as well as the types and contents of clay minerals especially for the clay minerals with 2:1 structure (Zhu et al., 2003). Although anionic surfactants could be expected to adsorb less than nonionic surfactants for most mineral surfaces, they are subject to loss by precipitation (Yang et al., 2007). Clearly, successful surfactant use to enhance remediation goes beyond selection of a surfactant (or surfactant system) that will efficiently solubilize organic solutes and should attempt to minimize surfactant losses by adsorption and precipitation in soil environments. The tendency of anionic surfactants to precipitate and nonionic surfactants to adsorb can be reduced by using mixtures of anionic and nonionic surfactants (Yang et al., 2005b, 2006). Moreover, such mixed anionic–nonionic surfactant system exhibit synergistic solubilization for solutes such as PAHs and NAPLs because the formation of mixed micelles to reduce their CMC and consequently prohibit the partition of nonionic surfactant to NAPLs (Zhu and Feng, 2003; Zhao et al., 2006). Mixed anionic–nonionic surfactant systems, therefore, can be expected to play an important role in the development of commercially viable surfactant systems for enhanced remediation processes.

A key issue of the applications of surfactants in remediation of contaminated soils is the toxicity of synthetic surfactants, which may pose a threat to the environment and ecological systems. Extensive toxicological data on aquatic organisms have been reported for anionic surfactants (Lewis, 1991). Cationic surfactants are potent germicides (Lawrence, 1970). Use of naturally occurring surface-active compounds such as biosurfactants would allay these concerns because they are readily biodegradable (Mulligan et al., 2001; Zhu and Zhang, 2008). Moreover, biosurfactants may be produced in situ and thus cheaper than synthetic surfactants (West and Harwell, 1992).

9.4.4 Effects of Surfactant on Uptake and Degradation by Microorganisms

It is widely accepted that the bioavailability of pollutants is limited to the dissolved portion of the compound in the aqueous phase (Scow and Hutson, 1992). Surfactants, because of their enhanced solubilization of hydrophobic compounds at concentrations above their CMCs (Kile and Chiou, 1989; Edwards et al., 1991; Zhu and Feng, 2003; Zhao et al., 2006), have been successfully used to desorb contaminants from contaminated soils and make contaminants to dissolve in the aqueous phase (West and Harwell, 1992; Tiehm et al., 1997; Yang et al., 2006). Due to the ability of surfactants to increase the apparent aqueous concentration of poorly soluble compounds, various surfactants, therefore, have been expected to increase the bioavailability and the accessibility of HOCs to microorganisms and thus HOC biodegradation (Edwards et al., 1991; Tiehm, 1994; Tsomides et al., 1995; Guha et al., 1998). To better understand the factors involved and the current state of knowledge in this field, a search of the literature concerning the influence of commercial surfactants and biosurfactants on microbial metabolism has been conducted. Due to the direct interaction of surfactants with microorganisms, it appears that steric or conformational compatibility of surfactants with cell membrane lipids and enzymes is an important metabolic factor (Rouse et al., 1994). Although the surfactants increased biodegradation of HOCs in some cases (Aronstein and Alexander, 1993; Rouse et al., 1994; Zhang and Miller, 1994; Guha and Jaffé, 1996a, 1996b; Zhang et al., 1997; Brown et al., 1999), in other cases either no effect or strong inhibition on biodegradation has been observed (Laha and Luthy, 1991, 1992; Falatko and Novak, 1992; Rouse et al., 1994; Deschenes et al., 1996; Bramwell and Laha, 2000; Cort and Bielefeldt, 2002). Because of the toxicity of synthetic surfactants, they may irreversibly damage the cellular envelope and inhibit microbial activity, and consequently reduce the uptake and degradation of the target pollutants (Rouse et al., 1994). Even the bio-surfactants, which is essentially biodegradable and nontoxic relative to synthetic surfactants and can have specific compatibilities with the cell envelope structures of the microorganisms that produce them, they still might produce inhibitory effects on cell structures of other microorganisms (Falatko and Novak, 1992; Rouse et al., 1994). Nontoxic surfactants can also lead to inhibitory effects on biodegradation of HOCs. For readily biodegradable surfactants, their inhibitory effects might be from the lack of the dissolved oxygen concentration in the system because the surfactant degradation lowers the dissolved oxygen concentration (Tiehm et al., 1997; Goudar et al., 1999; Mata-Sandoval et al., 2001). Another possible mechanism, by which surfactant micelles might inhibit biodegradation of contaminants, is the hydrophilic micellar surface, which may form a barrier blocking the interaction of microorganisms with the pollutant partitioned in the micellar core (Rouse et al., 1994), that is, the bioavailability of contaminants is limited to the portion associated with surfactant monomers outside the micellar phase (Volkering et al., 1995; Grimberg et al., 1996). However, other researchers (Guha and Jaffé, 1996a, 1996b; Guha et al., 1998) demonstrated that a fraction of the micellar HOCs is directly bioavailable to bacterial cells (i.e., the micellar HOCs can be directly transferred to the bacterial cell, rather than indirectly bioavailable where it must be released into the aqueous phase prior to being taken up by the bacterial cell). This direct bioavailability of HOCs from the micellar core to the cell can be quantified and depends on the surfactant types, surface characteristics of the biomass, surfactant concentrations, and the mixing conditions (Guha and Jaffé, 1996a, 1996b; Brown, 2007). A recent study by Brown and Al Nuaimi (2005) indicates that sorption of surfactants onto the bacterial cell surface occurs with varying levels of hemi-micelles, which may impact the bioavailable concentration of HOCs at the cell surface and is important governing surfactant-enhanced bioavailability (Brown, 2007).

Three possible pathways were assumed to interpret how and whether HOCs can enter into the bacterial cell (Figure 9.21) and then be available for biodegradation in the presence of surfactants (Guha and Jaffé, 1996a, 1996b; Brown, 2007). The first pathway, depicted as pathways (a) in Figure 9.21, is transfer of the HOCs in aqueous phase into the cell. The second pathway, depicted as pathways (b), is direct transfer of the HOCs in micellar-phase into the cell. The first pathway is considered for the case when biodegradation is controlled by the aqueous-phase HOC transfer into the cell. The second pathway, representing the micellar-phase HOC transport into the bacterial cell, is composed of two mass transfer processes: (1) the transport of the micelles containing HOCs from the bulk fluid to the cell, and followed by dynamic transfer of the micellar HOCs to adsorbed hemi-micelles on the cell surface upon micellar breakdown, and (2) the transport of the HOCs from the hemi-micelles into the bacterial cell. The pathway (b) assumes that all micellar HOCs transferred to the cell upon micellar breakdown is bioavailable and that the HOC gradient across the cell wall is driven by the micellar HOC concentration. The third pathway, depicted as pathway (c), assumes no

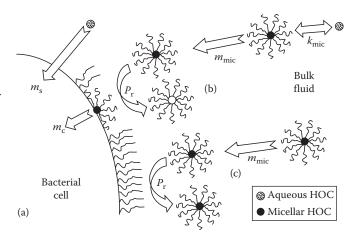

FIGURE 9.21 Pathways for an HOC to enter the bacterial cell. Pathway (a) is transport of aqueous HOC into the cell. Pathway (b) is direct transfer of micellar HOC to adsorbed surfactant hemi-micelles, with subsequent transport into the cell. Pathway (c) depicts a limiting case where no hemi-micelles are formed, resulting in micellar HOC not directly bioavailable. Note that the micellar HOC is always indirectly bioavailable via partitioning into the aqueous phase and subsequent transport into the cell through pathway (a). (Reprinted with permission from Brown, D.G. 2007. Relationship between micellar and hemi-micellar processes and the bioavailability of surfactant-solubilized hydrophobic organic compounds. Environ. Sci. Technol. 41:1194–1199. Copyright 2007 American Chemical Society.)

hemi-micelles formation on the cell surface and thus the micellar HOC cannot be directly transferred to the cell. This assumption, developed from the sorption results of surfactants on cell surface (Brown and Al Nuaimi, 2005; Brown, 2007), is in agreement with the theory that hydrophilic micellar surface may form a barrier that can block the interaction of microorganisms with the pollutant partitioned in the micellar core (Rouse et al., 1994). The pathways (b) and (c), independent of whether hemi-micelles form, describing micellar HOC transport into the cell would vary as a function of the hemi-micelle formation on the cell surface and the ability of those hemi-micelles to partition the HOCs.

The bioavailable HOC concentration ($C_{\rm bio}$, mg L⁻¹) can be defined as follows (Guha and Jaffé, 1996a, 1996b; Brown, 2007):

$$C_{\text{bio}} = C_{\text{aq}} + fC_{\text{mic}} \tag{9.22}$$

where $C_{\rm mic}$ (mg L⁻¹) and f (unitless) are the micellar HOC concentration and the fraction of micellar HOC that is directly bioavailable.

The bioavailability factors (f), for the alkyl polyethoxylate surfactants $(C_{12}E_y)$, were found to decrease with the increase of surfactant concentrations and the numbers of ethylene oxide groups (Figure 9.22) (Brown, 2007). Therefore, the effect of surfactants on HOC bioavailability enhancement (C_{bio}) , in Equation 9.22) is a result of the interplay between C_{mic} and f (Figure 9.22). This interplay results in a range of surfactant concentrations that provides enhanced bioavailability, and surfactant concentrations outside of this range can reduce the overall HOC

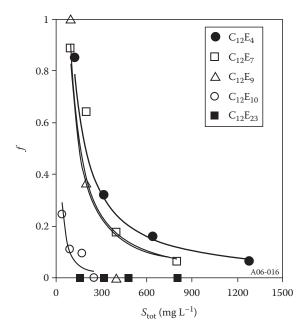

FIGURE 9.22 Bioavailability factor (f) plotted as a function of surfactant structure and concentration (S_{tot}) for the $C_{12}E_y$ surfactants with phenanthrene used as the HOC. (Reprinted with permission from Brown, D.G. 2007. Relationship between micellar and hemi-micellar processes and the bioavailability of surfactant-solubilized hydrophobic organic compounds. Environ. Sci. Technol. 41:1194–1199. Copyright 2007 American Chemical Society.)

bioavailability (Brown et al., 1999). It was also shown by Brown et al. (1999) that both the presence of soil and the total mass of HOCs in the system can strongly affect the HOC bioavailability, which leads to that the addition of surfactants could reduce HOC bioavailability even if f is nonzero. Although the bioavailability is important for HOC degradation, it is also important to

note that bioavailability alone is not an indicator of the ability of surfactants to enhance the HOC biodegradation rate. The biodegradation rate is also a function of the ability of the bacterial culture to utilize this enhanced bioavailability. The addition of surfactant may increase the bioavailable concentrations of compounds, but it will have negligible effect on the biodegradation rate when the ability of the bacterial culture is not high enough to utilize the bioavailable HOCs enhanced by the surfactant.

9.4.5 Effects of Surfactant on Uptake by Plants

Traditionally, the major pathway for the plant uptake of HOCs was shown to occur via the aqueous phase of the soil (Paterson et al., 1990; Alkorta and Garbisu, 2001; Chiou et al., 2001). Therefore, the use of surfactants to enhance the apparent aqueous solubility of HOCs has also been expected to enhance their bioavailability for plant uptake. In field experiments, some surfactants at certain concentrations have been observed to enhance the uptake and accumulation of p,p'-DDE by specific C. pepo (zucchini) (White et al., 2006, 2007). In these studies, however, decline of the uptake and accumulation of p,p'-DDE by C. pepo (zucchini) was observed with addition of surfactants, suggesting the enhancement of plant uptake was limited to cultivar specifics, the added surfactants and their concentrations. In a model ecosystem (water-lava-plant-air), Li et al. (2001) and Jiang et al. (2005) also observed reduced uptake of HOCs in plant roots in the presence of a nonionic surfactant (Tween 80) and an anionic surfactant (linear alkylbenzene sulfonate).

Several studies have been conducted in a hydroponic system to examine the uptake rate of HOCs by plant from water in the presence of surfactants at concentrations below or above CMCs (Gao et al., 2006, 2008; Zhu and Zhang, 2008; Sun and Zhu, 2009). As an example shown in Figure 9.23a, it was observed

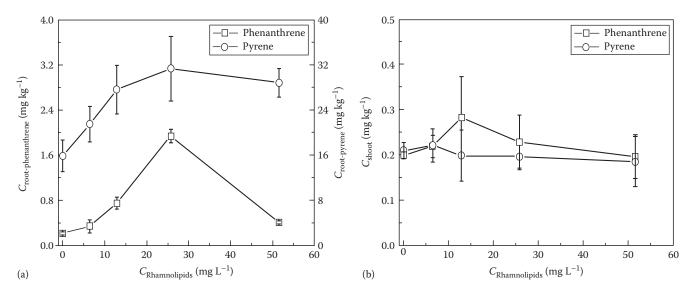

FIGURE 9.23 Concentrations of phenanthrene and pyrene in plant root (a) and shoot (b) after 288 h as a function of rhamnolipid concentration. (Reprinted from Zhu, L., and M. Zhang. 2008. Effect of rhamnolipids on the uptake of PAHs by ryegrass. Environ. Pollut. 156:46–52. Copyright 2008, with permission from Elsevier.)

in these studies that surfactant at concentrations lower than the respective CMC value could enhance the HOC uptake in plant roots, whereas surfactants at higher concentrations may inhibit the plant uptake. In addition, surfactants have no effects on the HOC levels in plant shoots (Figure 9.23b). The enhancement of HOC uptake in plant roots by relatively low concentration surfactants can be attributed to the permeability increase of ryegrass root cells by surfactants (Zhu and Zhang, 2008). The reduction of HOC uptake in plant roots by relatively high concentration surfactants might result from (1) the phytotoxicity of added surfactants to damage the plant cell and inhibit the plant growth (Gao, 2004; White et al., 2007), (2) the desorption of HOCs from root surface into the culture solution by the surfactants (Li et al., 2001; Jiang et al., 2005; Zhu and Zhang, 2008), and (3) the micellar HOCs are inaccessible and unavailable for the plant uptake (Li et al., 2001; Jiang et al., 2005).

Surfactants in the environment are well documented to have effects on the fate and behavior of organic chemicals by alternating their solubilization and mobilization, sorption/desorption in soil and sediments and microbial bioavailability. Although efforts have been used to explore their effects on the mineralization, metabolism, and uptake of organic chemicals by plants and their transportation in plants (Li et al., 2001; Jiang et al., 2005; Zhu and Zhang, 2008), present experimental data available in the literature are not enough to estimate the rate and the extent of plant uptake for HOCs in the presence of surfactants.

9.5 Conclusions

Overall, the fate of AOPs in the soil environment is a result of the AOP distribution in soil-related phases including soil solid mixtures, air, water, plant, and microorganisms. The aqueous phase, soil water, is the most important one among these phases for the AOP distribution because the aqueous phase acts as a medium that allows AOPs transfer from one phase to another and links with other phases. Without an aqueous phase, no direct transfer of AOPs can take place between soil-related phases. Soil physicochemical and biological interfacial processes describing the direct distribution of AOPs between aqueous phase and other phases, therefore, govern the fate of AOPs in the soil environment. Although these processes for AOPs are dynamic, they are commonly considered to be at an apparent equilibrium because the time for AOP distribution is long enough to reach the equilibrium in the environment. Changes in the equilibrium of AOPs in any of these processes may result in corresponding changes in the others. As such, these processes must be understood both individually and cooperatively in order to successfully predict the fate and risks of AOPs in the soil environment.

Sorption by soil solids determines the immediate biological availability of AOPs by decreasing the aqueous AOP concentration, retarding AOP release from soil to water or sequestrating AOPs in soil matrix, which potentially affects the fate and transport of AOPs in the soil environment. Soil is perceived as a dual sorbent for AOPs, in which the SOM functions not only as a linear partition medium but also a nonlinear adsorption medium.

SOM composition, aromaticity, and polarity have significant influence on the partition and nonlinear adsorption. Other soil components such as carbonaceous materials may also be important for nonlinear adsorption though their amount in normal soils may be low and their adsorption may be suppressed by the coated SOM. Nonlinear adsorption exhibits "competitive" and "irreversible" phenomena. The competitive behavior is expected to result in an increase of bioavailability for soil adsorbed AOPs by other solutes, while the irreversible sorption can decrease AOP bioavailability. In soils, multiple organic chemicals are commonly observed. Therefore, the decrease of AOP bioavailability generated by the irreversible behavior could be partly offset by the competition of the co-existing competitors. In single-solute system, the total nonlinear sorption, including either the linear partition fraction or the nonlinear adsorption fraction, can be estimated approximately from the soil organic carbon/matter content (f_{oc}/f_{om}) and chemical K_{ow}/S_{w} using the obtained empirical relationships between sorption coefficients and f_{oc}/f_{om} as well as between organic carbon/matter content normalized sorption coefficients and chemical K_{ow}/S_{w} . This sorption estimation also presents a potential way to predict the bioavailability, transport and fate of AOPs in the environment. However, the estimation of AOP sorption and the consequent bioavailability, transport, and fate of AOPs in natural systems could be more complex than that in the single-solute system because of the competitive sorption of multiple solutes in soils and irreversible sorption.

Plants and microorganisms have the ability to take up, accumulate, and degrade AOPs. The extent of AOPs to be taken up and the consequent accumulation and degradation depends on the bioavailability and toxicity of AOPs as well as the plant and microorganism species and population, which is also controlled by the factors such as nutrient supply, soil moisture, and temperature. A number of researchers have related the uptake of organic chemicals to the lipid content, and employed the lipid content to predict the contaminant uptake and accumulation. However, few data are available for the lipid content of plants and microorganisms and it may not be practicable to determine the lipid content for a wide range of species. Other components of plants and microorganisms such as cellulose and plant lignin may also have the ability for AOP uptake and accumulation, which needs to be addressed in future. Moreover, there is little information on what extent of AOPs in plants could be degraded and on the toxicity of the metabolites and bound AOPs.

Techniques to promote or decrease one interfacial process of AOPs could be employed in the engineered applications of soil and subsurface remediation. For example, cationic surfactants can promote the sorption of AOPs by soils, and thus their addition to soils can inhibit the transfer of AOPs from soil to plant, organisms, and surface/ground water. However, anionic and nonionic surfactants decrease the sorption of AOPs by soils, and thus can be added to water to enhance the washing efficiency and removal of AOPs from contaminated soils. Surfactants may also enhance the bioavailability of AOPs for the uptake and degradation by microorganisms and plants, which can be employed in the phytoremediation and bioremediation of contaminated soils. However, it is

important to investigate the limiting steps of AOP bioavailability and degradation rate before surfactants are designed and used for the enhanced remediation purpose. Moreover, minimizing losses from sorption and precipitation, environmental acceptability, balanced biological degradation, and the cost of surfactants must be addressed in designing and selection of surfactants for remediation. More importantly, the addition of surfactants for remediation should not add to the deterioration of soils and pose a new threat to the environment and ecological systems.

10.1 Introduction

The fate of nutrients and pollutants in soil and other porous geomedia in the Earth's surface depends on feedbacks and intimate couplings among physical, chemical, and biological processes. At small distances in this realm are the molecular-scale interactions that occur when nutrients and pollutants are introduced to a rich soil geochemistry of lithogenic solutes, organics, and particle surfaces, including those that are formed from organic and inorganic weathering processes. A premise of this chapter is that the fate and transport of nutrients and pollutants in the environment is highly dependent on the structure, dynamics and interactions of organic and inorganic secondary products of biogeochemical weathering. If that premise is correct, then once introduced to a soil environment, the fate of nutrients and pollutants must depend on the dynamic behavior of these secondary products. Since aqueous geochemical conditions in soils change on a hydrologic event basis as well as along fluid flow paths, one expects that the metastability and reaction kinetics of these secondary products and co-associated nutrients and pollutants will likewise behave dynamically in time and space.

Physicochemical processes that occur along flow paths in soil include (1) aqueous complexation, (2) redox, (3) sorption and flocculation, (4) nucleation and growth of inorganic and organic weathering products, (5) hetero-aggregation to form micro-aggregates, and (6) pore structure formation and associated limitations on advection and diffusion. These nano- to microscale interactions are then superimposed in the field by consolidation of hetero-aggregates into a macro-structured porous media with emergent properties of pedon- to field-scale heterogeneity and preferential fluid flow.

10.1.1 Critical Zone Interfaces

Soil component interactions lead to the formation of interfaces and aggregates that are central to soil function and therefore affect the fate of pollutants and nutrients (Figure 10.1). Heterogeneous reactions among soil solids, liquids, and gases affect the capacity of this portion of the Earth's surface to contribute to the "membrane" that sustains water and soil quality (Colin et al., 1992). This finite capacity of soil to detoxify pollutants and support ecosystem primary productivity is then modulated by soil

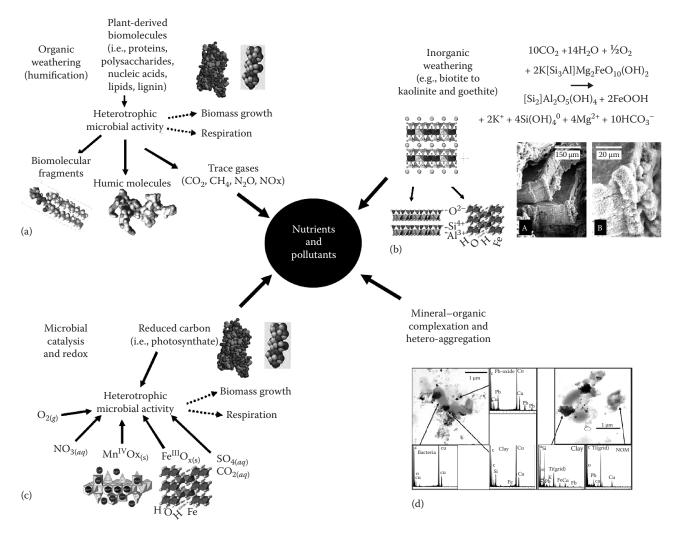

FIGURE 10.1 (See color insert.) Types of physicochemical and biological reactions affecting biogeochemical interfaces and the fate of pollutants and nutrients in soil systems. (a) Organic weathering (i.e., humification) processes involve the biotic and abiotic degradation of plant- and microbially derived biomolecules into biomolecular fragments and associated humic substances. (b) Inorganic weathering processes include the incongruent dissolution of primary minerals to form high specific-surface-area secondary clays and (oxyhydr)oxides that can coat the surfaces of primary minerals (shown in inset—halloysite coating the surface of biotite mica "books," from Kretzschmar, R., W.P. Robarge, A. Amoozegar, and M.J. Vepraskas. 1997. Biotite alteration to halloysite and kaolinite in soil-saprolite profiles developed from mica schist and granite gneiss. Geoderma 75:155–170. Copyright 1997, with permission from Elsevier.) (c) Microbial catalysis and redox reactions drive geochemical transformations as part of the set of alternative TEAPs in microbial respiration, such as the reductive dissolution of manganese (IV) and iron (III) oxides (MnOx and FeOx shown here are birnessite and goethite) with consequences for sorbed contaminants; (d) Mineral-organic complexation gives rise to complex heteroaggregates of secondary mineral particles, humic substances and microbial cells that constitute much of the reactive interface in soils. (Image from Perdrial, N., J. Perdrial, J.-E. Delphin, F. Elsass, and N. Liewig. 2010. Temporal and spatial monitoring of mobile nanoparticles in a vineyard soil: Evidence of nanoaggregate formation. biogeochemical processes. As discussed in this chapter, finite and dynamic capacity is reflected in the sensitivity of soil biogeochemistry to inputs and changes in environment, including anthropogenic effects. As one open system component of Earth's terrestrial surface, soils change in response to the structure and function of superimposed vegetation and underlying bedrock, as well as the meteoric forcing and interceding fluid fluxes. The entirety of that system, termed the *critical zone* (CZ), exhibits an open system character, strong disequilibrium, and dynamic reaction chemistry (NRC, 2001).

Because of the diversity of surfaces (Figure 10.1b) and the catalytic activity of resident microbial species (Figure 10.1c), geomedia have the capacity for sorption (retention) and chemical transformation (e.g., oxidation–reduction) of a wide range of solutes that affect water quality. Of particular interest to human health is the behavior of nutrients, metals, metalloids, and polar or nonpolar organic pollutants (see Chapter 8). In some cases, pollutants tend to traverse the CZ largely unimpeded (e.g., some polar organics and weakly sorbing oxyanions), whereas in many cases, the CZ appears to have a robust capacity to sequester

influent atmospheric, water, or waste pollution (e.g., many transition metals and hydrophobic organic contaminants [HOCs]). In any case, with respect to controlling the transport behavior of nutrients and pollutants in the CZ, soil interfacial reactions are paramount.

10.1.2 Biogeochemical Disequilibria

What drives the reactions is the set of geochemical disequilibria characteristic of open, biologically active, soil systems. Mineral weathering in the presence of biota is fueled by the thermodynamic instability at Earth surface conditions of (i) resident mineral phases and (ii) reduced carbon. These two distinct sets of reactants, one deriving from rock and the other from biomass, interact with water to create the most complex of all Earth surface environments: a multicomponent porous medium with extremely high solid-liquid-gas interfacial area, teeming with microbes and their metabolic products, and hosting large biogeochemical gradients even at micrometer-scale distances (Young and Crawford, 2004; Laverman et al., 2007; Hinsinger et al., 2009; Chapter 6). As a result of these characteristics, soils are capable of sequestering enormous pools of organic carbon, recycling nutrients fixed by the terrestrial biosphere, and remediating anthropogenic toxins. These essential ecosystem services tend to be provided most effectively by those soils whose reaction chemistry promotes the formation of meta-stable, high surface area, biogeochemical weathering products.

Through direct impacts on gas, liquid, and solid phase chemical dynamics, it is now well documented that biota play a prominent role in defining the rate and trajectory of these weathering reactions. What has been less well appreciated until recent years is the extent to which resident microbiota capture the energy liberated from these coupled mineral-organic transformation reactions, while also affecting their rate and trajectory. Biogeochemical reactions among minerals, organics, and microbes in disequilibrium soil systems support the reproduction and growth of diverse microbial communities and their large range of metabolic strategies. If there is energy accessible from an electron transfer reaction (i.e., negative ΔG), there are often microorganisms that have evolved the metabolic capability to promote the reaction and capture the energy liberated (Newman and Banfield, 2002). The intervention of microbiota and their metabolic byproducts in geochemical cycles affects not only reaction rates but also the specific nature (and hence subsequent reactivity) of reaction products. The characteristics affected by these interactions include the chemical composition, crystallinity, size, and surface reactivity of colloidal soil components (Monger et al., 1991; Konhauser, 1997; Toner et al., 2004).

The remainder of this chapter focuses specifically on *coupled* biological, physical, and geochemical processes that affect the transport and fate of nutrients and pollutants in soils. The following topics are discussed in turn: (1) biosynthesis and humification, (2) bio-physicochemical weathering processes, (3) reactivity of organo-mineral heteroaggregates, and (4) microbial intervention in metal cycling. Emphasis is placed on the

dynamic nature of the soil system, one where biotic and abiotic components and processes are subjected to tight interplays and feedbacks. A close examination of these interactions indicates that they are a key to better resolving and predicting the fate of nutrients and pollutants in the CZ. Particular emphasis is given to the process-mediating role of organic matter that is mobile in the aqueous phase. Although consisting of both dissolved and colloidal forms, this material is traditionally referred to as "dissolved" organic matter (DOM—that which passes through, for example, 0.45 µm membrane filtration), and this definition is used in the present chapter as well.

10.2 Biosynthesis and Humification

Plants and autotrophic microorganisms that colonize the irradiated surface of soil play a central role in the formation of biogeochemical interfaces by transforming radiant energy to chemical form during photosynthesis. This process harnesses extraterrestrial energy to fuel soil biogeochemical weathering (Kelly et al., 1998; Berner et al., 2003; Taylor et al., 2009). Upon exudation or senescence, biogenic natural organic matter (NOM) is the primary source of carbon and energy for a complex food web of chemoheterotrophic organisms that hydrolyze and oxidize it, either partially to form biomolecular fragments and humic substances, or completely to form CO_2 and H_2O (Figure 10.1a). These products create a geochemical environment that promotes subsurface mineral transformation reactions, alters the chemistry of particle surfaces, and influences the speciation and mobility of redox active nutrient and pollutant elements (e.g., C, N, S, Fe, Mn, Cr, As).

Near the soil surface, NOM is frequently a major component of the porous matrix, particularly in humid environments, because the high influx of plant litter and tissue exudates results in formation of both discrete organic residues and mineral surface coatings. As a result, surface soil exhibits the highest biomass and activity of soil organisms. Organic matter decomposition by soil fauna and microorganisms leads to the release of CO₂ and essential nutrient elements (e.g., N, P, S), and production of dissolved and colloidal organic matter (DOM), including the formation of humic substances by molecular aggregation and extracellular enzymatic or mineral surface-mediated reactions (Piccolo, 2002; Huang, 2004). This region is also influenced by the highest density of plant roots and their mycorrhizal associations that not only take up nutrients from the soil solution, but respire CO₂, and release protons (to maintain charge balance) and organic root exudates (e.g., low-molecular weight organic acids, enzymes, siderophores, polysaccharides, biosurfactants) (Arocena et al., 2004; Taylor et al., 2009). Some of these exudates are strong chelating ligands, including siderophores and low molar mass organic acids, that enhance mineral dissolution and release nutrients to solution (Landeweert et al., 2001; Huang and Germida, 2002; Calvaruso et al., 2006; Kraemer et al., 2006).

Root exudates and root turnover also serve as carbon sources for many microorganisms living in the rhizosphere, which themselves release biomolecules into the local microenvironment via cell exudation and lysis. Extracellular biomolecules may strongly adsorb to nucleating precipitates and mineral surfaces where they influence surface-controlled processes such as crystal growth (Lee and Reeder, 2006), ligand-promoted dissolution (Liermann et al., 2000), ion adsorption, and colloid deposition and release (Kretzschmar et al., 1995). In addition, biological uptake may promote the weathering of certain primary minerals by depleting the pore water of rock-derived nutrient elements. For example, K+ uptake by plants can increase the rate of mica weathering in soils (Hinsinger et al., 2006). Therefore, the rhizosphere around active plant roots often exhibits steep micrometer to millimeter scale gradients in pH, dissolved ligand and nutrient concentrations, and microbial activity (Marschner et al., 1986; Hinsinger et al., 2006). While plant roots and microorganisms are known to accelerate mineral weathering reactions via release of reactive chemicals, the details of these processes and their distribution in space remain poorly resolved (Jones, 1998; Jones et al., 2003; Akter and Akagi, 2005).

10.3 Coupled Biogeochemical Weathering Processes

10.3.1 Formation of Reactive Interfaces and Fate of Lithogenic Nutrients

The near subsurface environment is composed of highly complex associations among primary and/or secondary minerals, NOM, plant roots, microorganisms, aqueous solutions (pore water), and gases of varying composition (Chorover et al., 2007; Hinsinger et al., 2009). Since many of the relevant reactions are surfacecontrolled, interfacial characterizations under environmentally relevant conditions are essential. However, accurate characterization of interfacial chemistry in soil and sediment poses unique challenges and it cannot be done by measuring the bulk solid phase composition. In particular, discontinuous thin films of organic and inorganic material often coat underlying mineral surfaces. Although they may be present at trace levels, these "surface modifiers" significantly alter interfacial chemistry relative to that of the underlying solids, and thereby control surface charge, solute partitioning, and colloidal behavior (Davis, 1982; Bertsch and Seaman, 1999; Kretzschmar et al., 1999). Surface sensitive methods (e.g., atomic force microscopy, x-ray photoelectron spectroscopy, x-ray reflectivity, glancing incidence x-ray diffraction, attenuated total reflectance infrared spectroscopy) offer various advantages, and their conjunctive use often provides a more complete "picture" by giving complementary information on parameters such as chemical composition, functional group chemistry, surface topography, and patchiness (Gerin et al., 2003; Giesler et al., 2005; Wogelius et al., 2007; Cheng et al., 2008).

Since many of the reactions controlling nutrient and pollutant fate occur at solid–solution interfaces, the production and prevalence of finely divided mineral–organic particles is paramount. Leaching of water and solutes through the root and vadose zones drives incongruent weathering reactions that affect element mobility and chemical denudation. The secondary minerals formed from rock weathering include mainly layer silicates

(clay minerals) and various crystalline and short-range ordered (oxyhydr)oxides of iron, aluminum, and manganese (e.g., Figure 10.1b). Because of their high specific surface area ($10-800\,\mathrm{m}^2\,\mathrm{g}^{-1}$), these phases can occupy a large portion of the solid–water interface even when they are present at a low mass fraction. They also possess high charge and reactive site densities. These characteristics have important implications for wide-ranging environmental issues including metal(loid) and radionuclide fate in the subsurface. For example, (oxyhydr)oxide colloids tend to be "hot spots" for the sequestration of toxic transition metal species into strongly bound, and hence less bioavailable forms (Manceau et al., 2003), and polycrystalline coatings on primary silicate surfaces have been shown to control reactive transport of Pb²⁺ and Zn²⁺ in aquifer sediments (Coston et al., 1995).

10.3.1.1 Organo-Mineral Weathering Incongruency

The incongruent weathering of rock-forming primary silicates to give clay-sized secondary minerals proceeds in the presence of water, irrespective of biological activity. For example, the transformation of K-feldspar to form kaolinite:

$$2KAlSi_{3}O_{8(s)} + 2H^{+} + 9H_{2}O$$

$$\rightarrow \left[Si_{2}\right]Al_{2}O_{5}(OH)_{4(s)} + 4Si(OH)_{4} + 2K^{+}$$
(10.1)

occurs abiotically given sufficient fresh water. This incongruent dissolution can lead to surface coating of the feldspar with secondary weathering products. The formation of clay surface coatings on weathering primary minerals alters grain surface chemistry and passivates further mineral transformation. A study of field weathered albite, for example, showed precipitation of kaolinite on the grain surface as detected by a variety of techniques (atomic force microscopy, transmission electron microscopy, scanning ion mass spectrometry, and x-ray photoelectron spectroscopy), whereas the underlying albite surface itself was Al depleted (Nugent et al., 1998). Similarly, mica layers or "books" in the schist saprolite of an Ultisol were observed by SEM to become armored by their colloidal halloysite and kaolinite weathering products (Figure 10.1b) (Kretzschmar et al., 1997).

In the presence of high water flux and biological activity, such reactions can be accelerated or otherwise altered. For example, the production of complexing organic ligands such as dicarboxylic oxalic acid ($C_2H_2O_4$) by plant roots or microorganisms can alter the K-feldspar weathering reaction to give:

$$2KAlSi_3O_{8(s)} + 2C_2H_2O_4 + 4H^+ + 8H_2O$$

 $\rightarrow 2C_2O_4 - Al^+ + 6Si(OH)_4 + 2K^+$ (10.2)

where C_2O_4 –Al⁺ is the oxalate–Al complex with a net charge of +1. As written, the dissolution reaction in Equation 10.2 is congruent, no secondary solid is formed. However, while experimental studies have shown that feldspar dissolution in the presence of oxalic acid is indeed more rapid than in its absence, it is

also non-stoichiometric. Unlike Equation 10.1, however, oxalate reaction resulted in preferential dissolution of Al relative to Si (Stillings et al., 1996). One expects the oxalate–Al complex to be more mobile in the subsurface than monomeric inorganic Al, so its aqueous phase transport should be enhanced. But travel distance of the complex depends on several unknowns such as (1) hydrologic down gradient change in solution chemistry that could cause dissociation of the C_2O_4 –Al⁺ complex, (2) microbial degradation of the complexing organic at some constant or dynamic rate, (3) adsorption of the metal–organic complex (or some portion thereof) onto soil porous media surfaces, or (4) co-precipitation of the metal–organic complex with other DOM components as observed in B_{hs} horizons of Spodosols.

In the latter case, the resulting soil particles contain variously hydrolyzed Al and Fe bonded into a C backbone in a coagulated organo-metallic solid. Oxidative degradation of oxalate and/or dissociation of the complex down gradient from the weathering front would lead to liberation of Al and potential precipitation as gibbsite:

$$C_2O_4 - AI^+ + 0.5 O_{2(g)} + 2H_2O$$

 $\rightarrow AI(OH)_{3(s)} + 2CO_{2(g)} + H^+$ (10.3)

Thus, coupling between chemical, physical, and biological processes can bear directly on the types of reactive interfaces formed, and their distribution in space.

10.3.1.2 Microbial Role in Primary Mineral Weathering

A microbial role in weathering of primary minerals is now well established. Bacteria play an active role in the weathering of primary silicates by producing metal complexing agents, such as siderophores and other multi-dentate ligands. These ligands enhance the rate of mineral dissolution and increase the bioavailability of lithogenic nutrients. For example, in batch experiments, the rate of release of Fe from hornblende (an amphibole) was increased fivefold in the presence of Streptomyces sp., a rocksurface colonizing bacterial species (Liermann et al., 2000). The enhancement attributed to biosynthesis of a Fe-complexing catechol derivative that was characterized by mass spectrometry was comparable to that observed in the presence of a $24\mu M$ solution of a commercially available Fe-chelating siderophore, desferrioxamine mesylate (DFAM). The role of fungal hyphae and lichen in promoting the physicochemical weathering of primary silicates has also been widely reported. These organisms have the capacity to induce fractures along grain boundaries (Barker and Banfield, 1996), which increases interfacial area for chemical weathering attack. Fungal hyphae have a capacity to "tunnel" into feldspar grains, apparently in pursuit of cationic nutrients (Ca, K, Mg) (Hoffland et al., 2002). Solutions extracted from forest soil in close proximity to mychorrhizae exhibited a significantly greater extent of undersaturation with respect to nutrient-containing primary minerals as compared to non-mycorrhizal soil domains (Arocena and Glowa, 2000). Hence, it is clear that microorganisms contribute significantly to the weathering of rock, whereby lithogenic nutrients are released into bioavailable form.

10.3.1.3 Impact of Vascular Plants on Weathering versus Denudation

In respect to the fate of lithogenic nutrients (Ca, Mg, K, P), the distinction between chemical weathering (mineral transformation) and chemical denudation (element loss), has significant consequences for ecosystem productivity. Leaching losses of these solutes can diminish net primary production, whereas efficient recycling can enhance it. Recent experiments have shown that mass balance ratios of chemical weathering to denudation are higher in the presence versus absence of plants because of effective plant uptake and recycling of lithogenic nutrients (Balogh-Brunstad et al., 2008a). Weathering in the presence of plants results in greater incongruency, a higher proportion of secondary mineral phases and exchangeable nutrient cation concentrations, and diminished nutrient loss to leaching. In a related study of biotite and anorthite mixed into a silica sand (Balogh-Brunstad et al., 2008b), presence of bacteria and fungi were found to increase weathering fluxes compared to abiotic controls. Without a host plant (Pinus sp.) present, denudation rates were as large as weathering rates, that is, the weathering to denudation ratio was close to unity. Ectomycorrhizal seedlings produced the greatest weathering to denudation ratios (1.5), followed by non-ectomycorrhizal seedlings (1.3). The authors inferred that lithogenic nutrient loss was minimized in the planted systems because ectomycorrhizal hyphal networks and root hairs of non-ectomycorrhizal trees embedded in biofilm transferred nutrients to the host plant, thereby minimizing drainage losses.

It is now clear that plants enhance chemical weathering through a variety of mechanisms that together with their microbial associations include (1) exudate production (H+, siderophores, low molar mass organic acids), (2) soil respiration of CO₂, (3) evapotranspiration, and (4) soil physical stabilization (Taylor et al., 2009). However, they also diminish the nutrient losses associated with that weathering process, contributing to the accumulation and retention within soil of biogeochemically active weathering products. To the extent that biota contribute to the retention and increased bioavailability of lithogenic nutrients (e.g., Ca, Mg, K), one expects a positive feedback to net primary production (Berner et al., 2003).

The proliferation and growth of microbial cells and associated biofilms in soils contributes directly to the accretion of reactive surface area for the retention and transformation of nutrients and pollutants (Young et al., 2008). The microbial colonization of mineral surfaces is important for several reasons. Biofilm-derived organic debris impacts hydraulic conductivity by blocking pore throats and decreasing aperture sizes (Baveye et al., 1998). Also, microbial cells and their extracellular matrices increase system surface area, and since most low-temperature mass transfer processes are surface controlled, this may have

a large effect on chemical kinetics (Wogelius et al., 2007). More generally, soil biogeochemical weathering involves mineral dissolution–precipitation and oxidation–reduction reactions, and biota play a fundamental role in both.

10.3.2 Impacts of Organic Matter Infusion on Nutrients and Pollutants

Autotrophic photosynthate is the primary source of NOM and, therefore, of protons, electrons, and carbon in soil. Recent work suggests that once introduced to soil and water, plant-derived NOM is transformed into microbial byproducts, such that the majority of NOM resident in mineral soils is microbially derived (Guggenberger et al., 1994; Kogel-Knabner et al., 2008; von Luetzow et al., 2008). The resulting dissolved and colloidal organic matter can, therefore, exhibit similar molecular structures despite deriving from a range of biogeochemical sources, and this has been attributed to partial degradation mediated by heterotrophic microbes. For example, using size exclusion chromatography coupled to electrospray ionization-Fouriertransform ion cyclotron resonance (FTICR)-mass spectrometry, Reemtsma et al. (2006) analyzed fulvic acid (FA) isolates from three diverse sources (river, tarn, peat) and found that they exhibited remarkably similar carboxylated aliphatic molecular structures. This led the authors to conclude that FAs are metastable molecules that characterize a state of transition of more diverse precursor compounds during their oxidation in the environment. They propose that the elemental and structural regularity of FA molecules does not indicate one common precursor material and formation process, but rather the reworking of source materials in the environment and the valency of the three elements (C, H, O) from which most FA molecules are

The infusion of DOM into the subsurface has several important implications for biogeochemical reactivity. First, because of gas diffusion limitations, biologically active porous media can exhibit CO₂ partial pressures that are elevated up to 100 times above that of the atmosphere. As a result, pore water carbonic acid concentrations are likewise elevated (relative to water in equilibrium with the atmosphere), which increases acid attack on primary aluminosilicate minerals and promotes the formation of high-surface-area and surface-reactive, secondary mineral products. Secondly, biological activity is accompanied by aqueous- and solid-phase environments that are enriched in biogenic organic residues and metal-complexing ligands. These organic constituents strongly influence the rate and trajectory of mineral transformation, the speciation and mobility of metal and organic pollutants, and the long-term sequestration of atmosphere-derived carbon into mineral-organic complexes and aggregates. Polar fractions of DOM contain organic ligands that form stable complexes with major and trace metals, thereby increasing the metal mobility, whereas nonpolar moieties can solubilize hydrophobic organic pollutants and hence increase their leaching into groundwater. Thirdly, a large fraction of the

DOM leached from the root zone is biologically degradable, which means that it serves as a carbon and energy source for heterotrophic microorganisms living at greater depths. Gas phase $\rm O_2$ partial pressure may be diminished to trace levels in biologically active subsurface environments and microenvironments (such as within particle aggregates) because of its consumption during microbial and root metabolism as a preferred terminal electron acceptor for respiration.

10.3.2.1 Dissimilatory Reduction Reactions

Microbial catabolism of organic matter (OM) under O_2 -limited conditions drives important biogeochemical reactions, including redox transformations directly or indirectly coupled to the oxidation of OM (Figure 10.1c). Heterotrophic oxidation of NOM in O_2 -limited systems is coupled to the use of alternative terminal electron acceptors such as NO_3^- , Mn(IV), Fe(III), SO_4^{2-} , CO_2 , or organic carbon (Hunter et al., 1998). The use of these electron acceptors depends on their concentration, bioavailability and, importantly, their relative redox potential (with the most electronegative being preferred).

Such "dissimilatory" reduction reactions can also change the valence state and thus chemical speciation of redox-sensitive trace elements (e.g., As, Cr, U), with dramatic effects on their mobility and potential toxicity. These effects are often used as a tool in bioremediation of metal or metalloid contaminants. For example, dissimilatory reduction of U(VI) and Cr(VI) to U(IV) and Cr(III) can promote their removal from solution and incorporation into solid phases, diminishing their potential bioavailability (Valls and de Lorenzo, 2002). In contrast, other contaminant elements, such as arsenic, may become more mobile under anoxic conditions and this can have catastrophic impacts on human and ecosystem health. Mechanisms for As mobilization are multifaceted. Dissimilatory reduction of Fe(III) (oxyhydr)oxide sorbents results in release of sorbed As(V) to solution, and reduction of As(V) to the more mobile As(III) form is also catalyzed microbially (Smedley and Kinniburgh, 2002; Islam et al., 2004). Himalayan fluvial sediments that are naturally enriched in As are contributing to the degradation of anoxic shallow groundwater aquifers through such microbially mediated mechanisms, and this is contributing to a severe mass poisoning of rural populations in south and southeast Asia (Ahmed et al., 2004; Charlet and Polya, 2006; Polizzotto et al., 2008).

10.3.2.2 Reaction and Fate of DOM

The release of organic molecules and colloids from plants and microbes into the aqueous phase results in the transport of dissolved and colloidal organic matter from surface to subsurface soil environments (Herbert and Bertsch, 1995). The source of DOM includes recent photosynthate (throughfall, leaf litter, root exudates, decaying fine roots) and microbial exudates, as well as the leaching or decomposition of older, microbially processed soil organic matter (Guggenberger et al., 1994; Kalbitz et al., 2000; McDowell, 2003). The fact that the measured ¹⁴C age

of DOM ranges from hours to decades to thousands of years, indicates a correspondingly wide range of sources (Schiff et al., 1990). While it is sometimes assumed that newly abscised leaf litter is a principal source of DOM to subsurface mineral soils, particularly in forests, recent radiocarbon experiments conducted in forested ecosystems suggest that subsurface DOM derives more prevalently from the humified organic horizons or from the mineral soil itself rather than from leaching of the litter layer (Froberg et al., 2007). As a result of diverse sources, the composition of DOM includes plant and microbially derived biomolecules (proteins, polysaccharides, lipids, nucleic acids, lignin), their partial decomposition products (humic substances), and the complexes of these constituents with metals and other DOM components (Figure 10.1a and d).

Soluble DOM components interact via both covalent and non-covalent bonding interaction during the formation of humic substances, and these interactions can be effectively promoted by other soil constituents (Hedges, 1988; Piccolo, 2002; Sutton and Sposito, 2005). Covalent bonding occurs, for example, when amino acids react with sugar molecules in aqueous solution to produce *Maillard* reaction products (Ikan et al., 1996), or when phenolic compounds undergo oxidative coupling. While these reactions tend to be slow in abiotic aqueous solution, the presence of catalytic oxidizing agents, particularly Mn(IV) oxides such as birnessite, or microbially derived exoenzymes such as laccase, can greatly accelerate reaction kinetics (Jokic et al., 2001, 2004).

10.3.2.3 DOM Labile Structure and Reactivity

A thorough understanding of the molecular structure of NOM itself, including the DOM portion, remains a challenge, despite its clear importance to interfacial chemistry in soils and sediments (Hedges et al., 2000; Kelleher and Simpson, 2006). Improving that understanding drives an active area of research and employs state of the art tools in environmental analytical chemistry (Leenheer and Croue, 2003; Sutton and Sposito, 2005). Novel approaches, particularly those that combine computational methods with soft-ionization, mass spectrometry, multidimensional nuclear magnetic resonance (NMR) and other spectroscopic techniques are providing new insights (Diallo et al., 2003; Kelleher and Simpson, 2006). For example, while it has previously been thought that colloidal organic matter (e.g., humic acid [HA]) is dominated by high-molecular-weight polymerized degradation products of biomolecules, studies in the last 10 years suggest that these are instead supra-molecular structures comprising a large number of smaller molecules ranging in size from 100 to 2000 Da (Piccolo, 2001; Ferrer et al., 2002; Piccolo and Spiteller, 2003; Reemtsma and These, 2003; Rostad and Leenheer, 2004; Kelleher and Simpson, 2006). The smaller molecules, which are bound together in clusters via hydrophobic interaction, hydrogen bonding, and polyvalent cation bridging give rise to aggregates with macromolecular characteristics whose apparent molecular weight corresponds to 10,000-100,000 Da (Leenheer et al., 2001; Simpson, 2002; Simpson et al., 2002). These clusters undergo aggregation and disaggregation as function of solution chemistry, with clustering being favored in the presence of polyvalent metals such as Ca, Al, and Fe (Romkens et al., 1996; Romkens and Dolfing, 1998) and disfavored by low molar mass acids such as acetate that can form strong H-bonds with DOM constituents (Piccolo, 2001; Simpson, 2002). Studies of such aggregates at the nanometer and larger (colloidal) scale are beginning to reveal details of aggregate structure. Schumacher et al. (2005) used synchrotron scanning transmission electron microscopy (STXM) and C-1s near-edge x-ray absorption fine structure (NEXAFS) spectroscopy to study the chemical heterogeneity and functional group distribution of organic colloidal aggregates isolated from forest soils. Two distinct regions were observed in individual particles confirming the amphiphilic behavior of NOM. A hydrophilic, carboxylic region was concentrated in the outer portion, while a hydrophobic, aromatic region was concentrated in the interior.

Thus, aqueous phase organic matter constitutes a dissolvedto-colloidal continuum that is dominated by a complex mixture of intact and partly degraded biopolymers (proteins, carbohydrates, aliphatic biopolymers, and lignin) and their fragments. The transition from dissolved to colloidal potentially occurs as these molecular fragments and their co-associations are progressively aggregated into labile "supramolecular" structures through hydrogen bonding, cation bridging, and hydrophobic interactions (Piccolo, 2002; Sutton and Sposito, 2005). Biomolecules, constituent metals, and, in particular, the higher order structures that are formed by their intermolecular associations are characteristics of OM. This perspective suggests that the dynamic intermolecular associations of aqueous phase OM can be explored, in part, with tools that probe the nanoscale architecture of its particles. It seems reasonable to expect the selfassembly of NOM colloids in the presence of water affects their reactivity toward solutes and surfaces. For example, the crosslinking of humic molecules by polyvalent aluminum increases the nonlinearity and hysteresis of hydrophobic compound sorption to humic particle surfaces (Lu and Pignatello, 2004).

Mobile DOM participates in a multitude of geochemical reactions during transport that affect not only its own transport and partitioning behavior, but also that of co-associated nutrients and pollutants. These include (1) sorption—desorption, (2) aqueousphase and surface complexation, (3) mineral dissolution, and (4) oxidation—reduction. These are discussed in turn below.

10.3.2.4 Sorption–Desorption of OM

While the global environmental significance of mineral-stabilized organic matter is apparent (Houghton, 2005), the molecular-scale controls on the formation of stable mineral-organic complexes are not (Guggenberger and Kaiser, 2003; Chorover et al., 2004; Sollins et al., 2006). Unraveling the nature of NOM-mineral bonding, and the incorporation of these complexes into higher-order aggregated structures where carbon is protected from microbial attack, poses a unique challenge to biogeochemists. It requires a multifaceted approach that integrates field,

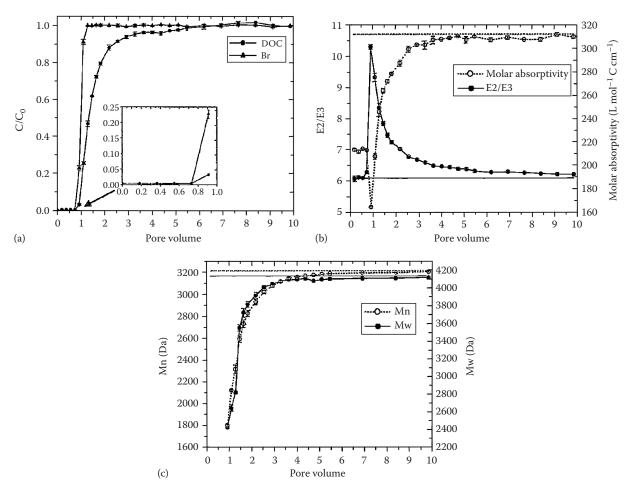

FIGURE 10.2 Reactive transport of DOM in repacked soil columns. (a) Breakthrough curve for DOM relative to an unreactive (bromide) tracer. (b) The time-evolution of UV absorbance properties of the DOM indicate the preferential retention at early times of more aromatic moieties. (c) Molar mass distribution of effluent fraction of DOM increases with time, indicating that higher molar mass compounds are preferentially retained. (From Guo, M.X., and J. Chorover. 2003. Transport and fractionation of dissolved organic matter in soil columns. Soil Sci. 168:108–118. With permission from Wolters Kluwer Health.)

modeling, and laboratory experiments with advanced analytical techniques that are only now becoming readily available.

The reactive transport of DOM can be considered in first approximation as analogous to a chromatographic process where compounds or colloids exhibiting the highest affinity for the solid phase are removed from solution closer to the surface, while more soluble components are transported to depth. The fact that DOM is a multicomponent mixture leads to its sorptive fractionation during transport. For example, reactive transport experiments with terrestrial DOM show that the breakthrough of organic carbon in packed Ultisol columns is retarded relative to a bromide tracer (Figure 10.2a). Furthermore, molar absorptivity (Figure 10.2b), apparent molar mass (Figure 10.2c), and DOM hydrophobicity (not shown) were observed to increase toward influent values over the course of the experiment. Hence, those fractions of DOM comprising greater aromaticity, hydrophobicity, and molecular size are preferentially adsorbed during transport, whereas smaller, more aliphatic and hydrophilic molecules remain in aqueous solution and are, therefore, mobilized to greater

depth (Guo and Chorover, 2003). Similar DOM fractionation processes have been reported in column-scale and field-scale studies of aquifer sands (Dunnivant et al., 1992; McCarthy et al., 1993), as well as in batch experiments with specimen oxyhydroxides (Zhou et al., 2001).

While retention of DOM on marine sediments is strongly correlated with the specific surface area of mineral sorbents (Mayer, 1994), this parameter alone is not a sufficient predictor of organic carbon in soils (Kaiser and Guggenberger, 2000). Analysis of a large data set on surface and subsurface soils indicates that the prevalence of (oxyhydr)oxides of Al and Fe, in particular, appears to exert a stronger control on organic carbon storage than does mineral specific surface area alone (Figure 10.3). This finding is consistent with an increasing number of reports that highlight the role of Al and Fe oxides, particularly short-range ordered phases, in controlling organic matter stabilization in soils (Torn et al., 1997; Mikutta et al., 2006; Rasmussen et al., 2006; Chapter 2).

Several types of chemical bonding influence DOM uptake during transport. The strong affinity of DOM for the hydroxylated

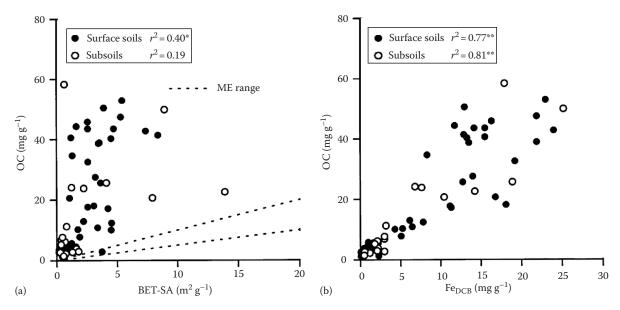

FIGURE 10.3 Organic carbon concentration versus (a) specific surface area (SA) in mineral soils (>10.6 g cm³) and (b) dithionite-citrate-bicarbonate extractable Fe for surface and subsurface forest soils (*, ** significant at p < 0.05 and p < 0.01 levels, respectively. (From Kaiser, K., and G. Guggenberger. 2000. The role of DOM sorption to mineral surfaces in the preservation of organic matter in soils. Org. Geochem. 31:711–725. Copyright 2000, with permission from Elsevier.)

mineral-water interface of hydrous oxide minerals is often attributed to the formation of inner-sphere complexes between carboxyl groups of DOM and singly coordinated metal centers on mineral surfaces (Filius et al., 2003). However, the extent to which adsorption results from inner-sphere versus outer-sphere mechanisms depends on DOM molecular composition (Yoon et al., 2005; Ha et al., 2008). Evidence for inner-sphere complexation comes from macroscale measurements of solution pH increase during DOM adsorption (Parfitt et al., 1977; Tipping, 1981). This is thought to result from mineral surface hydroxyl release (Gu et al., 1995) through a series of surface reactions such as

$$\equiv \text{Al-OH}_{(s)} + \text{H}_{(aa)}^{+} \rightarrow \equiv \text{Al-OH}_{2(s)}^{+}$$
 (10.4)

$$x (\equiv \text{Al-OH}_{2(s)}^{+}) + y \text{R-COO}_{(aq)}^{-}$$

 $\rightarrow (\equiv \text{Al-OOC-R})_{x} (\text{R-COO}^{-})_{y-x(s)} + x \text{H}_{2} \text{O}_{(aq)}$ (10.5)

where

"≡" indicates a surface functional group

x and *y* are the stoichiometric coefficients of protonated surface hydroxyls and sorptive DOM anionic ligands undergoing reaction

Thus, $y \text{R-COO}_{(aq)}^-$ represents y moles of monodentate ligand, one mole of y-dentate ligand, or an intermediate status between those two.

As indicated by Equation 10.5, because of its polyelectrolytic character, adsorption of DOM can result in configurations at the interface where the organic molecules adopt an adsorbed

conformation in which a substantial number of their anionic functional groups are not directly interacting with the oxide surface because of steric and electrostatic constraints. This concept has been incorporated into the Ligand and Charge Distribution (LCD) model of Weng et al. (2006). In the LCD model, ion binding to oxides, as described by the Charge Distribution MUlti SIte Complexation (CD-MUSIC) model (Hiemstra and van Riemsdijk, 1999), is integrated with ion binding to humic substances, as described by the nonideal competitive adsorption (NICA) model (Koopal et al., 2005) to effectively predict the sorptive interaction between DOM and iron (oxyhydr)oxides as a function of pH, ionic strength, and DOM concentration. The capability of the LCD model to predict FA adsorption hinges on the formation of inner-sphere carboxylate surface complexes (as depicted in Equation 10.5) as the primary driver. That is, modeling of electrostatic interactions alone is insufficient to fit experimental data (Weng et al., 2006).

A ligand exchange reaction such as that shown above is consistent with several infrared spectroscopy studies of reactions occurring when pristine oxides are reacted with DOM solutions (Gu et al., 1995; Chorover and Amistadi, 2001). Low molar mass organic acids, such as oxalate and lactate, likewise show inner-sphere complexation in attenuated total reflectance Fourier transform infrared (ATR-FTIR) data (Yoon et al., 2005; Ha et al., 2008). However, Yoon et al. (2005) studied adsorption of IHSS reference fulvic and HAs at the boehmite (γ -AlOOH) interface across a wide range of surface coverage using ATR-FTIR spectroscopy. They concluded that ligand exchange, even at low adsorbate concentrations, was a minor contributor to adsorption, and that fulvate/humate was adsorbed primarily in outer-sphere coordination, presumably via electrostatic and H-bonding interaction. Soil-relative humidity

likely also plays an important role in complexation, as a shift from predominantly outer-sphere to predominantly inner-sphere coordination was observed for several dicarboxylic organic acids upon drying (Kang et al., 2008). Hence, there remains a need for further investigation of the relative importance of ligand exchange versus outer-sphere complexation as mechanism for DOM adsorption at (oxyhydr)oxide surfaces.

Adsorption of DOM to the surfaces of layer silicate clays may potentially involve inner-sphere complexation at edge aluminol groups (Kubicki et al., 1997), but retention on basal surfaces of expansible clays likely involves weaker cation or water bridging, H-bonding, and/or hydrophobic sorption, especially for low-charged clays (Feng et al., 2005; Sposito, 2008). Spectroscopic studies indicate that organic matter associated with clay minerals either after adsorption experiments or upon sampling from field soils tends to exhibit higher aliphaticity, lower carboxyl group content, and lower overall polarity than that which adsorbs to hydrous oxide surfaces (Parfitt et al., 1997; Feng et al., 2005; Ghosh et al., 2009).

10.3.2.5 Mineral-Organic Solid-Phase Reaction Products

The amphiphilic properties of DOM are postulated to affect not only transport processes, but also the architecture of mineralorganic complexes in the weathering zone (Wershaw, 1993; Kleber et al., 2007). Polar functional groups bond to polar mineral surfaces via metals, oxygen atoms, and intervening water molecules. Exposed nonpolar (aliphatic and aromatic) groups may then interact with similar nonpolar DOM moieties from solution to form bilayer-like or multilayered structures, where the organic coatings are held together by the same hydrophobic, H-bonding, and cation bridging interactions that stabilize DOM aggregates. That is, once an organic coating is established, further adsorption of DOM does not necessarily involve bonding to the mineral surface, but could instead involve complexation with existing adsorbed OM, perhaps via H-bonding, cation bridging, or hydrophobic interactions. As discussed above, such intermolecular associations within organic aggregates have been identified in aqueous suspensions of DOM (Piccolo, 2002; Simpson et al., 2002; Sutton and Sposito, 2005). As a result, models of intra-organic association have been extended to explain adsorption at progressively coated mineral surfaces. For example, Kaiser and Zech (1998) found that progressive adsorption of DOM to the B_s horizon of a forest soil led to displacement of hydrophilic DOM and retention of the hydrophobic fractions, suggesting that organic-organic associations become more important at higher surface loadings.

A conceptual model of this "self-assembly" of organic molecules and fragments into a complex mineral-organic architecture was proposed recently by Kleber et al. (2007). Whereas pristine mineral surfaces are known to vary in their affinity for DOM functional groups and molecular types (e.g., Chorover and Amistadi, 2001), the model of Kleber et al. (2007) suggests that once a mineral surface coating is formed, mineral-organic complexes present a multilayered architecture irrespective of underlying mineral

type that includes a zone of hydrophobic interaction derived from the organic sorbate itself. The particle–solution interface in the model then becomes a zone of exchanging DOM fragments that enter and exit the organic realm of the sorbent surface in response to dynamic changes in solution chemistry (Figure 2.3).

Recent studies have implicated, in particular, poorly crystalline Al and Fe oxides in the stabilization of NOM against microbial degradation (Torn et al., 1997; Mikutta et al., 2006). Such stabilization processes affect the capacity of soils to store the largest Earth-surface pool of otherwise labile carbon and, therefore, they exert strong control over atmospheric CO2 and its radiative forcing effects (Houghton, 2005). The formation of stable NOM-mineral complexes can also have pronounced effects on surface charge and molecular adsorption properties of the solid phase, as well as influence the aggregation behavior of colloidal particles (Kretzschmar et al., 1998; Heidmann et al., 2005). These mineral-organic associations create rough and chemically heterogeneous surfaces in contact with the pore water, thereby affecting the advective-diffusive transport and deposition of solutes and colloidal particles, including sorbed pollutants, in the subsurface (Kretzschmar et al., 1999).

Mineral-organic complexes in soils appear to exist in an array of associations, but most commonly in aggregated form. Constituents of such aggregates include partially humic-coated clay surfaces, and their incorporation into nanometer- to micrometer-sized micro-aggregates in which OM is sometimes encrusted by colloidal minerals (Chenu and Plante, 2006). These micro-aggregates assemble into higher-order macro-aggregate structures (Six et al., 2000). Both mineral-surface interaction and physical-aggregate occlusion have the potential to impede or diminish enzymatic degradation of OM. Hence, accurate characterization of formation and destruction dynamics of these mineral-organic aggregates is a key to predicting stabilization of organic C in soils. Furthermore, an improved understanding of mineral-organic architecture at the molecular to particle scale will greatly assist in elucidating the important role that OM plays in sequestration of inorganic and organic nutrients and contaminants in soil.

10.3.2.6 Aqueous Phase and Surface Complexation Effects

Upon introduction to soil from plant or microbial tissue abscission, exudation or lysis, photosynthetic biopolymers are attacked, principally by extracellular enzymes that cleave them into smaller (e.g., oligomeric to monomeric) molecular weights, which tend to be more soluble. Once in the aqueous phase, such fragments can adsorb to surfaces, serve as a C source for microbial growth, and undergo reaction with ions or other soluble biotic components. Organic components in soil solution can form complexes with solutes released from rock weathering, nutrient cycling, atmospheric deposition, and anthropogenic sources. By forming such complexes, DOM can play a significant role in the transport of nutrients and pollutants in structured soil. For example, in reactive transport experiments conducted with undisturbed soil columns Camobreco et al. (1996) found that columns treated with

DOM-complexed metals had peak effluent concentrations that were 30%, 26%, 28%, and 27% of influent for Cd, Zn, Cu, and Pb, respectively. In the absence of DOM, peak effluent concentrations were largely unchanged for Cd and Zn, but were substantially reduced to 15% and 12% for Cu and Pb, respectively. This indicates that the relative importance of aqueous organic complexes for mobilizing metal pollutants depends on their stability (i.e., greater for Cu and Pb). However, affinity of the metal–DOM complexes for soil particle surfaces must also be considered. In the same study, homogenized soil columns were found to retain all added metals, whether the metals were added in water or as organic complexes, which highlights the importance of preferential flow paths to the transport of metals in structured soil.

Complexation reactions of DOM can enhance the migration of oxyanion nutrients (e.g., phosphate) or pollutants (e.g., arsenate/ arsenite or selenate/selenite), but by different mechanisms than are observed for the cationic transition metals. It is postulated that DOM can compete directly with oxyanions for adsorption sites on hydroxylated minerals. Inner-sphere complexation of phosphate and arsenate has been attributed to ligand exchange at singly coordinated surface hydroxyl groups. Ligand exchange at singly coordinated hydroxyls results in direct bonding of

oxyanions to Fe(III) or Al(III) metal centers. Arsenite shows a higher affinity for doubly coordinated hydroxyls, and both As(V) and As(III) are likely adsorbed outer-spherically as well, depending on concentrations (Fuller et al., 1993; Waychunas et al., 1993; Sun and Doner, 1996; Chapter 8). Aluminum metal centers can serve as bonding sites even in poorly crystalline aluminosilicates. Since DOM can compete for adsorption at the same surface hydroxyl groups, its presence in solution can diminish both phosphate and arsenic uptake.

If humics and oxyanions are competing for the same sites, their fate depends on the effects of oxyanion–DOM selectivity. However, sorptive competition can also result from electrostatic effects. Several authors have sought to measure these effects in competitive adsorption experiments and modeling, and the results indicate the importance of both oxyanion speciation and DOM composition. For example, arsenate competes more effectively than arsenite for adsorption to goethite in the presence of peat HA or Suwannee River FA (Grafe et al., 2001). Lower molar mass DOM (e.g., FA) appears to diminish arsenate adsorption to goethite more effectively than does higher molar mass DOM (e.g., HA) as shown in the top two graphs of Figure 10.4 (Weng et al., 2009). Likewise, presence

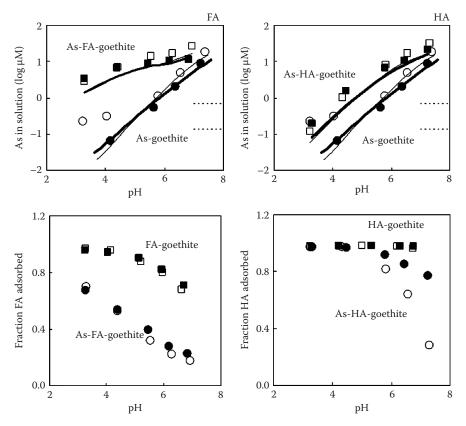

FIGURE 10.4 Competitive adsorption of arsenate (AsO₄³⁻) and fulvic acid (FA, left side) or HA (right side) to the surface of goethite. (With permission from Weng, L., W.H. van Riemsdijk, and T. Hiemstra. 2009. Effects of fulvic and humic acids on arsenate adsorption to goethite: Experiments and modeling. Environ. Sci. Technol. 43:7198–7204. Copyright 2009 American Chemical Society.) Top graphs show arsenate remaining in solution in the presence and absence of FA or HA, and bottom graphs show fractional adsorption of FA and HA in the presence and absence of arsenate. The FA and HA samples have apparent molar masses of 0.68 and 13.2 kDa, respectively (measured by size exclusion chromatography). Open symbols are for 1.0 mM NaNO₃, closed symbols are for 10.0 mM NaNO₃. Experimental conditions: 1.0 g L⁻¹ goethite, 0.15 mM arsenate, 50 mg L⁻¹ FA/HA.

of arsenate more strongly diminishes FA than HA sorption (Figure 10.4, bottom). This may be attributable to the tendency for arsenate to form inner-sphere complexes at goethite surface hydroxyls that are also sites for FA carboxylate complexation (Weng et al., 2006). Alternatively, it has been argued that since FA is smaller in size than HA, it adsorbs more closely to the goethite surface, and thereby more strongly impacts goethite surface charge (Weng et al., 2009). Similarly, Xu et al. (1988) argued that FA that was adsorbed coulombically to aluminum oxide, diminished arsenate adsorption by increasing the net negative charge of the particle surface. Hence, either direct bonding site competition or surface charge repulsion may contribute to diminished arsenate adsorption in the presence of DOM. In addition to these particle surface effects, DOM can also mobilize oxyanions via the formation of ternary aqueous DOM-metal complexes, presumably by metal-bridging mechanisms, which diminishes the tendency of such oxyanions to form surface complexes (Bloom, 1981; Redman et al., 2002; Lin et al., 2004).

10.3.2.7 Bioligand-Mediated Mineral Dissolution

Even in the absence of direct surface interaction, metal-complexing organic ligands can promote mineral transformations by diminishing the relative saturation of the solution phase with respect to mineral constituents. However, organic ligands are also implicated in direct particle surface dissolution to the extent that they can promote the detachment of surface metal centers following ligand-surface-metal complexation. This latter reaction involves first the formation of an *activated precursor complex* wherein a structural metal that is part of the mineral surface becomes coordinated to an adsorbing organic ligand, followed by polarization of the remaining metal-oxygen bonds in the mineral structure, and metal-ligand detachment (Stumm, 1997; Brown et al., 1999).

These two distinct processes—ligand-promoted surface dissolution and aqueous-phase metal-ligand complexationlikely combine in biologically active soils to affect mineral bioweathering. An example of this is provided by the synergistic effect on goethite dissolution of oxalate, a common rhizosphere organic acid, and desferrioxamine B (DFOB), a microbially produced trihydroxamate siderophore (Cheah et al., 2003; Reichard et al., 2007). Batch steady-state and transient experiments indicate that the two types of biomolecules co-operate to enhance the release of Fe(III) from low solubility mineral surfaces as depicted in Figure 10.5. The kinetic model that best fits experimental data is one that includes fast oxalate adsorption to the goethite surface via ligand exchange with goethite surface hydroxyls followed by the slower production of an activated precursor surface complex (labile \equiv Fe-L, where L = oxalate). The synergistic effect comes into play because detachment of labile Fe-L into solution is promoted by the presence of "predatory" siderophores that capture Fe(III) from oxalate. This transfer of Fe(III) to siderophore increases the thermodynamic pressure for labile Fe-L desorption, and also recycles the catalyst, oxalate, for re-adsorption at the surface (Figure 10.5). Hence, the pulsed exudation of phytosiderophores that has been observed to occur diurnally likely results in a correlated pulsed bio-availability of nutrient Fe (Reichard et al., 2007).

This preceding example pertains to a relatively simple abiotic experimental system comprising goethite, oxalate, and DFOB in aqueous solution. Nonetheless, it illustrates the emergent complexities and potential synergies that are associated with multicomponent and heterogeneous mixtures. Such complexities are only amplified in biologically active soils as they exist in field settings. This is one reason why translating laboratory-derived understanding to field systems remains a grand challenge to soil scientists and CZ researchers.

10.3.2.8 Oxidation-Reduction

Even at the scale of individual aggregates, soils contain diverse microenvironments comprising minerals, microbes, and organics. Because of diffusion limitations, metabolically catalyzed redox reactions and the generation of acids and complexing agents lead to aqueous phase concentration gradients, mineral nucleation sites, and element speciation that are markedly different from the bulk solution (Templeton et al., 2003; Chan et al., 2004; Hinsinger et al., 2009). The chemical parameters pE and pH govern many reaction trajectories in soils. The fact that photosynthate and its transformation products are a principal source of electrons and protons in soils is readily seen by considering the oxidation half-reaction of glucose (the monomer of the plant polysaccharide cellulose and many other microbial polysaccharides) to form bicarbonate in soil solution:

$$C_6H_{12}O_6 + 12H_2O \rightarrow 6HCO_3^- + 30H^+ + 24e^-$$
 (10.6a)

Even when this reaction is coupled with the reduction half-reaction of dissolved O_2 (DO), net proton production is still apparent:

$$C_6H_{12}O_6 + 6O_2 \rightarrow 6HCO_3^- + 6H^+$$
 (10.6b)

Though degassing of $CO_{2(g)}$ can diminish the number of moles of $H_{(aq)}^+$ produced per mole of biomolecule oxidized, the aqueous phase protons produced by microbial oxidation of photosynthate and humics drive numerous reactions in soils, including particle surface charging (in turn affecting solute adsorption and colloidal dynamics) as well as proton-promoted mineral weathering (Equation 10.1).

In addition to serving as the primary source for electrons in soils, DOM plays an important role in soil redox reactions by functioning as an intermediary in microbial metabolic processes (Lovley et al., 1996; Benz et al., 1998) and by facilitating the cycling of metals, for example, Fe, that can exist in multiple oxidation states (Lovley et al., 1998). In particular, quinone–hydroquinone functional groups are thought to serve as reactive moieties in the oxidation–reduction of inorganic pollutants such as mercury, chromium, arsenic, and uranium

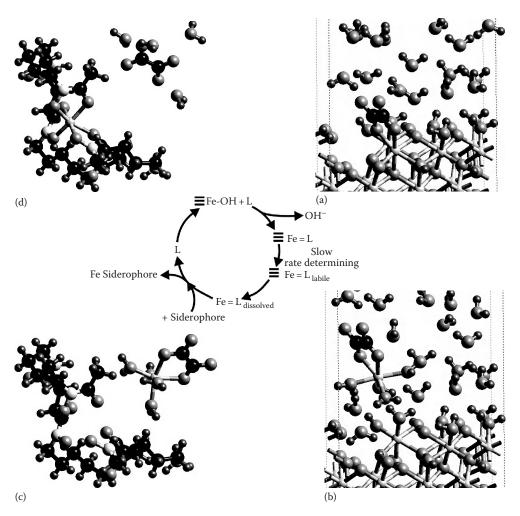

FIGURE 10.5 Schematic showing synergistic effects of oxalate and siderophore in goethite (α-FeOOH) dissolution. (a) Oxalate reacts adsorbs via ligand exchange to form a bidentate-mononuclear surface complex (Duckworth and Martin, 2001); (b) the labile Fe-oxalate surface complex is desorbed; (c) oxalate transfers Fe to DFOB, a high-affinity siderophore ligand; and (d) Fe forms multi-dentate, mononuclear aqueous complex with siderophore, and free oxalate is recycled. (Modified after Reichard, P.U., R. Kretzschmar, and S.M. Kraemer. 2007. Rate laws of steady-state and non-steady-state ligand-controlled dissolution of goethite. Colloids Surf. A Physicochem. Eng. Asp. 306:22–28. Copyright 2007, with permission from Elsevier, with molecular visualization created with Cerius² from Accelrys Inc, San Diego, CA; Courtesy of Professor James Kubicki, Pennsylvania State University.)

(Allard and Arsenie, 1991; Redman et al., 2002; Gu and Chen, 2003; Gabriel and Williamson, 2004), as well as organic contaminants such as nitroaromatic and organochlorine compounds (Schwarzenbach et al., 1990; Kappler and Haderlein, 2003). Evidence for the redox activity of quinone-like moieties derives from fluorescence and electron spin resonance (ESR) spectroscopies, as well as electrochemical data (Scott et al., 1998; Struyk and Sposito, 2001; Nurmi and Tratnyek, 2002). Quinone moieties in humic substances form free radical species, such as semiquinone, when they undergo a one-electron reduction. However, electrochemical titrations of humic substances have shown that HAs have electron transfer capacities that are much greater than that which is accounted for based on free radical concentrations alone (from ESR measurements) (Struyk and Sposito, 2001). This suggests the existence of other redox active moieties in DOM, possibly resulting from

redox-active heteroatoms (e.g., N or S), or inner-sphere metalorganic charge transfer complexes, such as the strongly bound Fe atoms in humic substances.

Redox character of DOM is not solely a function of its own chemical composition. For example, the electron transfer capacity of humic material has been shown to increase with solution pH (Matthiessen, 1995), which has been attributed to relaxation of humic molecules, which leads to increased availability of redox active functional groups. Aggregate structure of DOM also plays a role. Palmer and von Wandruszka (2009) found that the redox potential of humic substances was strongly dependent on the concentration of bivalent, but not monovalent, cations. Dynamic light scattering measurements of colloidal OM size showed that a redox potential shift was correlated with decreasing radius of the DOM aggregates in response to increasing bivalent cation concentration.

10.3.2.9 Microbial Adhesion

Microbial cells, especially bacteria and protozoa, can be transported over relatively long distances in porous media prior to attaching to mineral or organic surfaces (Hornberger et al., 1992; Schafer et al., 1998; Redman et al., 2004). Bacterial adhesion often involves the coating of substrata and growing cells with extracellular polymeric substances (EPS), prior to an incipient biofilm that evolves into a complex microenvironment at the solid–water interface. Because of the diversity of biomolecular and mineral surface structures and functionalities, adhesion of microbial cells to mineral surfaces has the potential to involve a multitude of biomolecule–surface interactions that can contribute to or diminish cell-surface adhesion. Steric and dispersion forces similar to those that act on bare and polymer-coated surfaces, are superimposed on a wide range of localized molecular bonding possibilities (hydrophobic, van der Waals, ion bridging, covalent).

As a result of the predominance of weakly acidic carboxyl, phosphoryl, and hydroxyl functional groups, microbial surfaces tend to exhibit net negative charge over a wide pH range

representative of natural waters. Thus, individual microbial cells may be transported over long distances in porous media. This can be beneficial when contaminant remediation requires microbiological augmentation (Scow and Hicks, 2005). Or, it can be detrimental when it involves the transport of pathogenic microbes (e.g., Cryptosporidium sp., Giardia sp., or Escherichia coli). Recent history contains several cases where pathogens have been transported in aqueous suspension through porous geomedia and into community water supplies (Curriero et al., 2001). Hence, an understanding of adhesion processes is essential. Mean field models, based on Derjaguin-Landau-Verwey-Overbeek (DLVO) theory of reactive particle transport and adhesion to surfaces, do not closely match experimental adhesion measurements because key interaction mechanisms of bio-particles and mineral surfaces are not included among the classical DLVO (van der Waals and electrostatic) forces (Ginn et al., 2002). More effective data fits for E. coli adhesion to silica, for example, were made when models included a steric term to account for the "polymer brush" surface of microbial

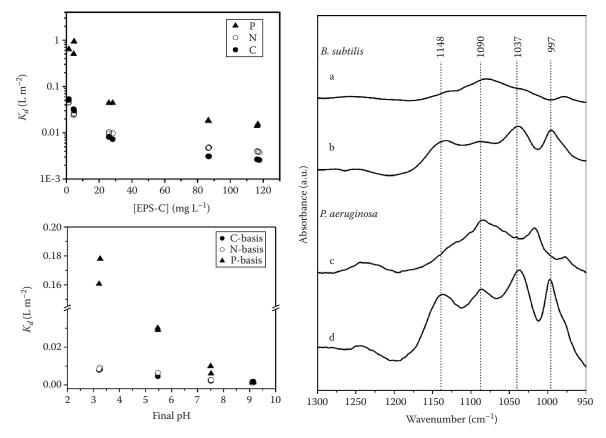

FIGURE 10.6 Left side shows macroscopic data on adsorption of EPS from *Bacillus subtilis* to the surface of α-FeOOH as a function of EPS concentration (carbon basis) (top left) and pH (bottom left). Data indicate preferential adsorption of P-containing moieties. (From Omoike, A., and J. Chorover. 2006. Adsorption to goethite of extracellular polymeric substances from *Bacillus subtilis*. Geochim. Cosmochim. Acta 70:827–838. Copyright 2006, with permission from Elsevier.) Right side shows attenuated total reflectance Fourier transform infrared (ATR-FTIR) spectra of EPS from *B. subtilis* and *Pseudomonas aeruginosa* either free in solution (a, c) or adsorbed to the surface of goethite (b, d). Emergence of new peaks for adsorbed EPS is indicative of formation of inner-sphere PO-Fe bonds as a result of ligand exchange. (With permission from Omoike, A., J. Chorover, K.D. Kwon, and J.D. Kubicki. 2004. Adhesion of bacterial exopolymers to alpha-FeOOH: Inner-sphere complexation of phosphodiester groups. Langmuir 20:11108–11114. Copyright 2004 American Chemical Society.)

cells (Camesano and Logan, 2000). In addition to providing the potential for steric effects and mixing entropy of the polymer brush, surface biomolecules also can enter into direct (e.g., covalent) bonding interactions with hydroxylated mineral surfaces (Parikh and Chorover, 2006). Laboratory and field experiments with microorganisms have shown that ferric oxyhydroxide coatings are important in the removal of microorganisms in saturated porous media, even in the presence of organic matter and phosphate, which can block microorganism attachment (Harvey and Ryan, 2004). As a sorbent for biomolecules, the siloxane surfaces of primary silicates and clay minerals differ significantly from the hydroxylated surfaces of Fe and Al (oxyhydr)oxides. Whereas the basal surfaces of clay minerals tend to effectively sequester aliphatic molecules such as lipids, the hydroxylated surfaces of hydrous oxides exhibit affinity for phosphorylated and carboxylated compounds.

Early adhesion processes likely involve some degree of mineral-surface conditioning film formation by free or cell-bound EPS. Microbial exudates and lysates comprise a mixture of polysac-charides, proteins, nucleic acids, and lipids whose relative affinities for mineral surfaces depend on the structure and functional group chemistry of the substrate surface, as well as solution chemistry conditions. Data on the adsorption of EPS from the bacterial strains $Bacillus\ subtilis$ and $Pseudomonas\ aeruginosa$ to the goethite (α -FeOOH) surface are shown in Figure 10.6. Macroscopic sorption data indicate that reaction of EPS with goethite favors preferential uptake of P-containing biomolecules relative to bulk C or N (left side of Figure 10.6). One explanation for this organic

P-selectivity comes from infrared spectroscopic data (right side of Figure 10.6) of goethite-EPS complexes indicating the ligand exchange of biomolecular phosphoryl groups at goethite surface hydroxyls (i.e., \equiv Fe-OP-R bonding). These infrared spectroscopic results are consistent with ab initio quantum chemical calculations of complexation of phosphodiester groups, such as those associated with nucleic acids, bonded to Fe metal centers (Omoike et al., 2004; Omoike and Chorover, 2006). ATR-FTIR spectroscopic studies of live bacterial-Fe oxide systems also show the formation of \equiv Fe-OP-R_(s) bonds, suggesting that cell-bound phosphorylated molecules also play an important role in whole cell adhesion to unconditioned oxide surfaces (Parikh and Chorover, 2006).

The transport of pathogenic microbial contaminants is likewise affected by mineral-microbe bonding interaction. As shown in the left side of Figure 10.7, the progressive coating of quartz sand surfaces with iron oxyhydroxide results in a significant decrease in Cryptosporidium parvum oocyst breakthrough from porous media columns, and an increase in adhesion, as reflected in the collision efficiency parameter, α (Abudalo et al., 2005). The right side of Figure 10.7 shows ATR-FTIR studies of oocyst surface functional group chemistry upon adhesion to uncoated (top) and iron-oxide-coated (bottom) surfaces. The data show that at the pH of the transport experiments, oocysts are adhered to Fe oxide surfaces through inner-sphere complexation of carboxylate groups at Fe(III) metal centers (Gao et al., 2009). Hence, in addition to the influence of electrostatic attraction for microbial adhesion to Fe oxide at this pH, direct bonding effects likely also play a role in retarding pathogen transport.

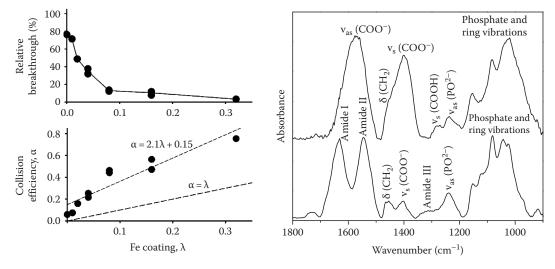

FIGURE 10.7 Macroscopic transport data left side shows that relative breakthrough decreases and collision efficiency increases for *Cryptosporidium parvum* oocysts as a function of the fraction of the Fe(III) oxide surface coating of a quartz sand at pH 5.6–5.8 and 0.1 mM NaCl. (With permission from Abudalo, R.A., Y.G. Bogatsu, J.N. Ryan, R.W. Harvey, D.W. Metge, and M. Elimelech. 2005. Effect of ferric oxyhydroxide grain coatings on the transport of bacteriophage PRD1 and Cryptosporidium parvum oocysts in saturated porous media. Environ. Sci. Technol. 39:6412–6419. Copyright 2005 American Chemical Society.) (Zeta potential of oocysts under these conditions was –10 mV.) Right side uses molecular spectroscopy to depict the mechanism. ATR-FTIR spectra of oocysts adhering to an uncoated (bottom spectrum) and α-Fe₂O₃-coated (top spectrum) internal reflection element surface indicates the inner-sphere complexation of oocyst carboxylate groups at hematite Fe(III) metal centers. (With permission from Gao, X., D.W. Mettge, C. Ray, R.W. Harvey, and J. Chorover. 2009. Surface complexation of carboxylate adheres *Cryptosporidium parvum* oocysts to the hematite/water interface. FIGURE 10.8 2D Vertical scanning interferometry image of *Shewanella oneidensis* colonization of a magnesite surface after 9h. The biofilm consists of taller (white) cells and associated lower (light gray) organic material. (From Davis, K.J., and A. Luttge. 2005. Quantifying the relationship between microbial attachment and mineral surface dynamics using vertical scanning interferometry (VSI). Am. J. Sci. 305:727–751. With permission.)

Following initial adhesion to mineral surfaces, further accumulation of cells and EPS can result in the formation of incipient biofilm, where the nature of biopolymeric exudates are driven partly by cell physiological response to the local interfacial environment. Indeed, Geoghegan et al. (2008) proposed that "cell attachment and related cell growth behaviour is mediated by macromolecular physics and chemistry in the interfacial environment. Ecological success depends on the genetic potential to favourably influence the interface through adaptation of the macromolecular structure." One example of a complex biofilm structure is depicted in Figure 10.8 where colonization of the magnesite (MgCO₃) surface by *Shewanella oneidensis* is visualized using vertical scanning interferometry (VSI) (Davis and Luttge, 2005). The image clearly shows local regions of higher cell topography (bright yellow) and lower regions comprised of the organic matrix (darker yellow).

10.4 Effects of Organo-Mineral Heteroaggregates on Nutrient and Pollutant Fate and Transport

The complexation of NOM and microbial cells with inorganic weathering products produces mineral-organic complexes whose architecture and chemistry are distinctly different from the constituent parts in isolation. These complexes and their aggregates control the storage and transport of organic nutrients in soil, and also present heterogeneous surfaces and diverse reactive sites to soluble pollutants. The surface chemistry of organo-mineral hetero-aggregates is sensitively dependent to the biogeochemical environment in which they are formed.

10.4.1 Surface Composition of Mineral-Organic Complexes

The influence of biogeochemical environment on surface chemistry of mineral-organic complexes is illustrated by considering data from a chrono-sequence of basalt-derived tropical forest soils that range in parent material age from 0.3 to 4100 thousand years. The total organic C concentrations for the A horizon (for soil

parent material ages of 0.3, 20, 150, 400, 1400, and 4100 ky) are, respectively, 19, 178, 188, 290, 131, and 40 g kg⁻¹. Corresponding organic C concentrations in the B horizon are 23, 114, 121, 81, 20, and 12 g kg⁻¹. Hence, the intermediate-aged soils contain the highest mass fraction of organic matter, consistent with their prevalence of poorly crystalline minerals (Torn et al., 1997). Figure 10.9 shows x-ray photoelectron spectroscopy (XPS) data that give the "surface enrichment" of organic carbon and nitrogen on soil particles from this chrono-sequence as determined from the C_{1S} or N_{1S} peak intensity relative to that measured within the particle bulk, following argon sputter of the surface layers (Mikutta et al., 2009). Surface accumulations of C and N relative to particle bulk are indicated by surface enrichment values greater than unity. Results for A and B horizons are shown. The XPS data show that the youngest soils (0.3ky) have significant enrichment of organic matter on particle surfaces, consistent with adsorption of DOM to the surfaces of primary minerals (plagioclase) that are predominant at early weathering stage and that are co-associated with smaller quantities of secondary precipitates (allophane and ferrihydrite). Conversely, the intermediate-aged soils (20–400 ky), which are highly enriched in poorly crystalline secondary minerals such as allophane and ferrihydrite, show negligible particle surface enrichment in organic matter relative to the particle bulk, despite the fact that these soils contain the highest concentration of organic matter overall. The oldest soils again show particle surface enrichments of organic C, which is consistent with the prevalence in those soils of organic matter adsorption to well crystallized secondary phases kaolinite, gibbsite, and goethite.

These results indicate a change in hetero-aggregate structure over the course of pedogenesis. Surface associated organic matter is prevalent in mineral-organic complexes at early and late weathering stages, when well-crystallized primary and secondary minerals are predominant, respectively. However, in the intermediate weathering stage, when such complexes comprise poorly crystalline minerals and organic matter, the XPS data suggest a solid phase that reflects greater mixing of organic and inorganic components at the nanoscale; that is, the data are consistent with hetero-aggregates wherein colloidal OM is coagulated into floccules with nano-particulate inorganic weathering products (Mikutta et al., 2009).

10.4.1.1 Surface Charge Effects

The impacts of such changes in mineral-organic structure on soil surface chemistry and, therefore, on the transport of nutrients and pollutants, are profound. One way to quantify them is to measure the variation in soil surface charge, which, in turn, affects adsorption-desorption of aqueous phase solutes (Chorover et al., 2004). The point of zero net proton charge (PZNPC) for the chrono-sequence soils is plotted on the right side of Figure 10.9 (Chorover et al., 2004). The PZNPC is defined as the solution pH value where net adsorbed proton surface charge density is equal to zero (Sposito, 2008). Therefore, it represents a measure of Brönsted acidity of soil particle surfaces, and the prevalence of positive or negative variable surface charge at a given pH. The PZNPC data shown here were obtained by discontinuous titrations of the soils

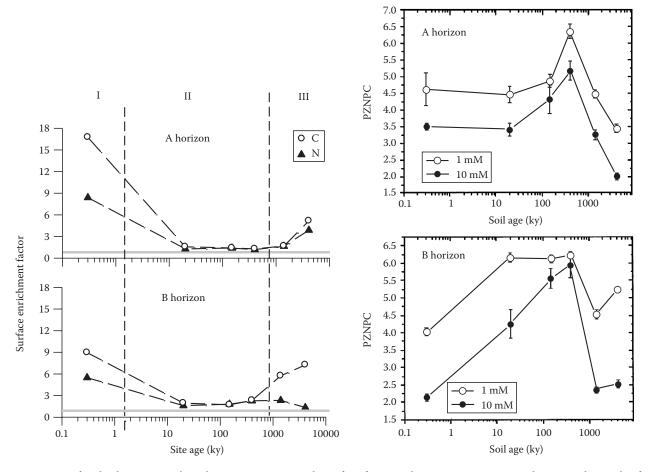

FIGURE 10.9 Left side shows x-ray photoelectron spectroscopy data of surface enrichments in organic C and N on soil particles from Hawaiian chronosequence. (From Mikutta, R., G.E. Schaumann, D. Gildemeister, S. Bonneville, M.G. Kramer, J. Chorover, O.A. Chadwick, and G. Guggenberge. 2009. Biogeochemistry of mineral-organic associations across a long-term mineralogical soil gradient (0.3–4100 kyr), Hawaiian Islands. Geochim. Cosmochim. Acta 73:2034–2060. Copyright 2009, with permission from Elsevier.) Right side shows surface charge (PZNPC) data on particles from the same soils (From Chorover, J., M.K. Amistadi, and O.A. Chadwick. 2004. Surface charge evolution of mineral-organic complexes during pedogenesis in Hawaiian basalt. Geochim. Cosmochim. Acta 68:4859–4876. Copyright 2004, with permission from Elsevier).

suspended in LiCl background electrolyte solutions at 1 and 10 mM ionic strength. The low PZNPC values for early and late weathering stages are consistent with masking of the underlying mineral surfaces by acidic functional groups of NOM (i.e., the pKa of carboxyl groups is ca. 3-4, whereas the PZNPC of iron or aluminum (oxyhydr)oxides, which predominate at the later weathering stages, is ca. 7-8 (Chorover, 2005). The higher PZNPC values for the intermediate-aged soils suggest that carboxylate and phenolate functionalities in NOM are highly complexed in these soils with monomers, dimers, or higher order polymers of Fe and Al. Such complexes are consistent with recent extendend X-ray absorption fine structure (EXAFS) spectroscopy studies of Fe coordination in organic soils, which show strong binding of hydrolyzed Fe dimers and trimers at organic surface functional groups (Gustafsson et al., 2007). High aqueous phase concentrations of Al and Fe in these soils derive from the solubility of poorly crystalline precipitates and the prevalence of DOM for ligandmetal complexation. The prevalence of Al and Fe on soil particle surfaces shifts the interfacial acidity of the soils to reflect that of OM-adsorbed hydrolyzing cations and their polymerized reaction products (Chorover et al., 2004).

Surface charge properties of mineral-organic complexes are closely linked to their dissolution behavior. For example, the intrinsic surface charge (σ_{in}) of the soil from the 1400 ky site is plotted as a function of pH in Figure 10.11a (open circles). Intrinsic surface charge, which includes the contributions from both proton adsorption-desorption and structural charge resulting from isomorphic substitutions, is negative throughout the pH range studied, but approaches zero (the point of zero net charge) as pH decreases toward 3.5. With increasing pH, σ_{in} increases in magnitude, reflecting increased negative surface charge. Correlated with the increase in negative surface charge is the dissolution of DOM (solid circles), indicating that proton dissociation of weakly acidic functional groups (e.g., carboxyl) promotes release of solid phase organic matter into solution (Figure 10.11a). Importantly, the release of DOM is linearly correlated with the dissolution of Fe, Al, and Si (Figure 10.11b), and the regression slopes give the number of moles of metal(loid) complexed with DOM per gram of carbon.

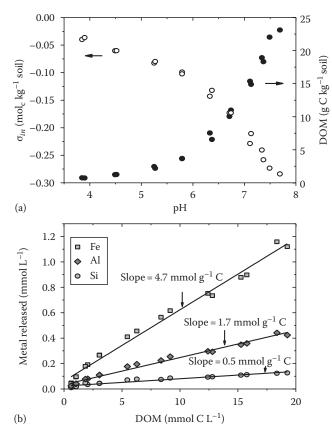

FIGURE 10.10 DOM-mediated metal release from a Plinthic Kandiudox Molokai, Hawaii (1400 ky soil shown in Figure 10.9). (a) Top graph shows intrinsic soil surface charge (moles of charge per kilogram of soil, right axis) and DOM release (grams of carbon per kilogram of soil, left axis) in 10 mM LiCl background electrolyte as a function of solution pH (total soil organic carbon = 125 g kg⁻¹. (From Chorover, J., M.K. Amistadi, and O.A. Chadwick. 2004. Surface charge evolution of mineral-organic complexes during pedogenesis in Hawaiian basalt. Geochim. Cosmochim. Acta 68:4859–4876. Copyright 2004, with permission from Elsevier.) (b) Correlated release of lithogenic metal(loid)s Fe, Al, and Si as a function of organic carbon dissolution. Soil PZNPC = 3.3 and PZNC = 2.1. Slopes of lines in (b) give millimoles of metal dissolved per gram of organic C, which for the sum of DOM-Al and DOM-Fe are comparable to the total carboxyl group content of DOM.

The sum of the values for Al and Fe (6.4 mmol g $^{-1}$ C) fall within the range commonly reported for moles of dissociable charge of soil DOM (Tipping, 2002), indicating a high degree of metal ion complexation. These results show that the pH dependence of Fe and Al dissolution from mineral–organic complexes in soil weathering environments can be distinct from that which has been observed for pure mineral phases such as goethite and gibbsite. The latter typically show *decreasing* metal dissolution with increasing pH for the pH range shown in Figure 10.10 (Stumm and Morgan, 1996).

10.4.2 Sorption of Inorganic Molecules at Mineral-Organic Interfaces

The term sorption represents a continuum of interfacial reactions that can lead to accumulation of nutrients or pollutants on

or within solid surfaces. When inorganic ions and molecules are first introduced to a mineral or organic interface, mechanisms of adsorption may include diffuse electrostatic attraction (e.g., Ca²⁺ or Cd²⁺ adsorption to the siloxane surface of montmorillonite or carboxylate groups of DOM), H-bonding (e.g., weakly acidic oxyanions at (oxyhydr)oxide surfaces), inner-sphere or covalent bonding (e.g., phosphate or arsenate ligand exchange at A-type hydroxyls on Fe or Al oxyhydroxides). As shown schematically in Figure 10.11, the adsorption process is a dynamic one, where the adsorbate may desorb back to bulk solution, or diffuse along the surface to higher affinity sites with larger bond number (e.g., ledge and kink sites). Inner-sphere complexes can give rise to a distorted form of sorbent crystal growth, and at higher surface loadings, adsorbate species may polymerize and grow into surface precipitates that alter surface reactivity, masking that of the underlying surface (Sposito, 2004). Hence, in the weathering environment, adsorbate speciation is nonstationary; and it undergoes an evolution subject to biogeochemical forcing. Changes occur on timescales that range from those of rapid water-ligand exchange on solute species (<10⁻⁹ s) to much slower changes in sorbent structure resulting from weathering reactions (>103 s) (Chorover and Brusseau, 2008).

Since local coordination strongly affects sorbate stability against chemical perturbations in soil solution (e.g., from hydrologic events), it is likewise expected that the aqueous

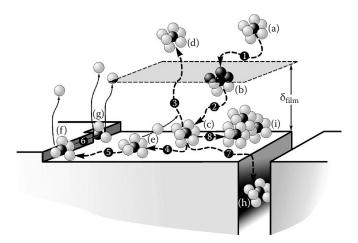

FIGURE 10.11 Schematic of ion sorption at the particle—water interface: (a) hydrated metal ion (water molecules are represented by light colored spheres surrounding the dark colored metal ion) approaching the surface via (1) bulk and (2) film diffusion. At the surface, the hydrated ion may (b) reside in the diffuse ion swarm, (c) form an outer sphere complex, (d) undergo desorption or (e) form an inner-sphere complex in association with loss of hydration water. Adsorbed ions may be desorbed (3) to bulk solution, or undergo (4, 5, 6, 7, 8) surface diffusion to form stronger complexes at higher affinity (f) ledge or (g) kink sites, undergo (h) diffusion into intraparticle pores, and/or to (i) sites of surface polymerization. (With permission from Springer Science + Business Media: Chorover, J., and M.L. Brusseau. 2008. Kinetics of sorption-desorption, p. 109–149. *In* S. Brantley, J. Kubicki, and A.F. White (eds.) Kinetics of water-rock interaction. Springer, New York.)

geochemical environment that accompanies sorbate formation exerts a strong control on the type of product formed. An array of environmental factors—such as sorptive species, pH, ionic strength, surface loading, and contact time—all affect the type of sorption complex or product that results. At short timescales and low sorptive concentrations, diffuse, outer and inner-sphere sorption is common, but as sorption occurs over extended timescales that approach those of sorbent transformation (e.g., mineral weathering), and also higher sorbate loadings, then surface nucleation and co-precipitation reactions are increasingly important to nutrient or pollutant fate (Schindler and Stumm, 1987).

10.4.2.1 Types of Reactive Sites

From the discussion above, it should be apparent that the types and densities of surface functional groups presented to the soil solution will depend on the biogeochemical environment in which the mineral-organic complexes were formed. Given the multicomponent complexity of natural soil particles and aggregates, there is no single analytical method that can provide a complete molecular-scale description of their surface chemistry. However, this is precisely why the conjunctive use of complementary macroscopic, microscopic, and spectroscopic approaches has contributed to significant advances in the past two decades (Brown et al., 1999; Sposito, 2004; Sparks, 2006; Hochella et al., 2008; Maurice and Hochella, 2008). Organic and inorganic moieties contribute to the interface in varying degrees, but not necessarily in proportion to their mass abundance (Bertsch and Seaman, 1999). This has important implications for sorption of metals, oxyanions, and organic pollutants.

For example, organic-rich soils that contain hydrolyzed Al and Fe in carboxylate or phenolate complexes may show much lower affinity for bivalent contaminant transition metals (e.g., Cd, Co, Ni) as a result of competition (Gustafsson et al., 2003, 2007). However, sites of organically complexed Al and Fe in humic-rich soils can serve as effective sorption sites for strongly sorbing oxyanions such as phosphate and arsenate (Bloom, 1981). Combining wet chemical methods with ATR-FTIR spectroscopy, Giesler et al. (2005) found that at high P loadings, phosphate formed precipitates with organically complexed Al and Fe in humus soils, whereas both adsorbed and co-precipitated species were formed when phosphate was added to soils with higher free iron oxide content. While precipitate formation is likely to be less favorable in soils with lower phosphate concentrations, the complexation of oxyanions with organically bound Fe and Al in soil humus may be of general importance to their transport and fate.

10.4.2.2 Diversity of Ion Sorption Mechanisms and Reactive Site Selectivities

Among the bivalent cations, strong differences exist with respect to their affinity for reactive mineral–organic particle surfaces. These differences can be related to their Lewis acid–base properties. Based on numerous molecular-scale spectroscopic studies (using XAFS, FTIR, and NMR), it is generally observed that the non-hydrolyzing Group II cations, Mg²⁺, Ca²⁺,

Sr²⁺, and Ba²⁺, which are hard Lewis acids, are weakly adsorbed in soils as outer-sphere complexes, particularly with hard Lewis base functional groups such as carbonate, sulfate, carboxyl, and phenolic or alcoholic OH. Hydrolyzing metals behave differently. The hydrolyzing first-row transition metal cations, Mn2+, Fe2+, Co2+, Ni2+, Cu2+, and Zn2+, are borderline Lewis acids and they tend to form stronger inner-sphere complexes with borderline and soft base (e.g., sulfite, pyridine) functional groups. Similarly, the soft Lewis acids, which are the hydrolyzing, highmass metal cations such as Cd2+, Hg2+, and Pb2+, tend to form stronger, inner-sphere surface complexes, particularly with soft base groups such as thiol, sulfhydryl, and lipophilic (e.g., C_2H_4) moieties (Richens, 1997; Sparks, 2005). Although there are currently experimental challenges to using molecular-scale techniques to determine the types of surface complexes that strong acid anions such as NO₃-, Cl-, and ClO₄- form on surfaces, they are generally thought to sorb to positively charged surfaces as outer-sphere complexes. Sulfate and SeO₄²⁻ can be sorbed as both outer-sphere and inner-sphere complexes, depending on environmental conditions, whereas most oxyanions that derive from dissociation of weak acids, such as molybdate, arsenate, arsenite, chromate, selenite, phosphate, and silicate, appear to be sorbed more strongly as inner-sphere complexes on clay edges and oxide surfaces, via a ligand exchange mechanism (Sposito, 2004).

10.4.3 Sorption of Organic Pollutants

Sorption mechanisms for organic pollutants are strongly dependent on the polarity and functional group chemistry of the sorptive compound. For polar molecules, surface interactions are analogous to those for inorganic ions, including ionic and/or covalent (i.e., outer- and inner-sphere complexation with surface metal or oxygen groups) and hydrogen-bonding interactions. For nonpolar compounds, van der Waals interaction and hydrophobic effects are dominant, and for this reason, NOM is the most important sorbent for HOCs. An emerging concern is the ever-increasing number of organic contaminants with widely ranging functional group composition and polarity are introduced into soil and water systems on a daily basis. These derive, in particular, from the widespread use of pharmaceuticals and personal care products, some of which have endocrine disrupting capability even at vanishingly low concentration.

10.4.3.1 Hydrophobic Organic Contaminants

As discussed above, OM's amphiphilic character includes sorption domains that are themselves relatively hydrophobic (e.g., aromatic and aliphatic regions) and these are thought to constitute important sorption sites for HOCs (Semple et al., 2003). HOC sorption–desorption in natural systems is often characterized by a rapid, reversible sorption–desorption process followed by a much slower, nonreversible stage. Observations of rate-limited, nonlinear, and competitive sorption for HOCs have led to the development of the "dual-mode" sorption model,

which presumes that solid phase NOM is composed of "soft rubbery" and "hard glassy" domains (Huang et al., 2003). Hydrated carbon components (biomolecules, most humic substances) are considered to comprise the expanded "rubbery" domain, whereas condensed carbon components (black carbon, some humin components, kerogen) are considered to comprise the "glassy" domain. The rubbery domain is represented as flexible and polymeric, wherein organic compound sorption is linear, noncompetitive and controlled by permeation interactions. The glassy domain comprises nanometer-scale pores in which retention—more akin to adsorption—occurs via sorbate interaction with pore walls. Sorption to pores in the glassy NOM is thought to be responsible for the nonlinear and competitive effects that are sometimes observed for HOC sorption. Despite a wealth of macroscopic data highlighting the importance of NOM to HOC sorption, the precise mechanisms responsible for the biphasic behavior and the molecular nature of HOC sorption sites are still poorly understood (Luthy et al., 1997; Ehlers and Loibner, 2006).

10.4.3.2 Trace Organic Contaminants of Emerging Concern

A wide range of emerging contaminants including pharmaceuticals and personal care products (PPCPs) and endocrine disrupting compounds (EDCs) have been measured in water sources throughout the United States (Kolpin et al., 2002). The presence of PPCPs and EDCs in streams has been attributed to widespread domestic and veterinary use of these compounds, their accumulation in wastewater (e.g., sewerage, lagoons), and wastewater treatment that is only partially effective in their removal prior to effluent discharge into the environment. Thousands of different pharmaceutical substances are used daily including painkillers, antibiotics, antidiabetics, β-blockers, contraceptives, lipid regulators, antidepressants, and impotence drugs. Effluent and biosolids from wastewater treatment plants are primary entryways for PPCPs and EDCs into the environment, much occurring with little recognition (Kinney et al., 2006). Only during the last decade has information concerning the concentration and environmental fate of these "emerging contaminants" been reported (Kummerer, 2001). Particular concern is now focused on EDCs because they are capable of eliciting physiological response among continuously exposed organisms at vanishingly low (part-per-trillion to part-per-billion) concentrations (Drewes et al., 2005).

Many EDCs are polar and tend to persist in wastewater effluents. The increased usage of treated wastewater for soil irrigation, as well as its discharge into surface and ground waters allows them to enter soils, the biosphere, and drinking water supplies (Snyder et al., 2003). Biosolids, which are often applied as soil amendments, can contain high concentrations (part-per-million to part-per-thousand on a dry mass basis) of hydrophobic EDCs such as nonylphenol and flame-retarding chemicals. In addition, it has been estimated that thousands of tons of antibiotics are used annually in the United States for livestock farming only (Kemper, 2008). The situation is complicated by the fact that many pharmaceuticals are transformed (oxidized, hydrolyzed,

or reduced) or subjected to conjugation processes in vivo before being excreted.

EDC/PPCPs vary considerably in terms of molecular structure, functional group content and physicochemical properties, even within a specific class of compounds. For example, the water solubilities of antibiotics range from the μg L-1 level (for polyethers—monensin and salinomycin) to thousands of mg L⁻¹ (tetracyclines—chloroteteracycline and oxytetracycline). The $\log K_{ow}$ values of these compounds vary commensurately, from 3.5 to -1.2. Thus, it is not surprising that distribution coefficients $(K_d \text{ values, which indicate the relative affinities of aqueous-phase})$ chemicals for solid-phase sorbents) among antibiotic compounds vary from 70-5600L kg⁻¹ for tetracyclines and quinolones to low values of 0.2–2 L kg⁻¹ for sulfonamides (Tolls, 2001). Nonetheless, most EDC/PPCPs tend to be more polar than persistent HOCs and, as a result, their sorption to surfaces is strongly influenced by the interaction of solution chemistry (pH and ionic strength) and sorbent type. For example, protonation of sulfoamines resulted in an increase in K_d (from 1 to 30) when the pH of mineral soil was decreased from 8 to 4 (Boxall et al., 2002). Higher binding of enrofloxacin was reported for montmorillonitic relative to illitic or kaolinitic soils (Tolls, 2001). The accumulation of ofloxacin at particle surfaces exhibits strong pH dependence (maximum adsorption occurring between the pK_{a1} and pK_{a2} of the compound) and binding mechanisms are distinctly different for silica (binding via heterocyclic N) versus alumina (Al chelation by carboxylate and carbonyl group) surfaces (Goyne et al., 2005). These studies underline the importance of considering polar functional groups, and combining macroscopic and spectroscopic studies for elucidating the binding of EDC/PPCPs at environmental surfaces.

Many EDC/PPCPs interact strongly with DOM in preference to hydrophilic mineral surfaces, though the mechanisms are not clear (Zhou et al., 2007). Tolls (2001) and Thiele-Bruhn (2003) suggested that the sorption of antibiotics to organic matter is not related solely to their hydrophobicity because K_d values for complexation with DOM are higher than would be predicted based on simple partitioning theory. Zhou et al. (2007) found that EDC sorption to aquatic colloids was enhanced for those colloids containing a higher mass fraction of organic carbon and, in particular, those colloids that have higher specific UV absorbance (i.e., greater aromaticity). Conversely, it is very likely that sorption to DOM and solid phase OM of more polar EDCs is governed by the same processes that control the "supramolecular" assembly of the humic substances themselves (Piccolo, 2002). Hence, while it is clear that DOM may strongly influence EDC/PPCP transport, the intermolecular interactions are likely to be multifaceted and include not only hydrophobic sorption but also ionic, covalent, and/or hydrogen bonding interactions.

10.4.4 Aging Effects

Prolonged sorbate–sorbent contact in the soil-weathering environment can, in some cases, result in diminished bioavailability of both inorganic and organic contaminants (Hatzinger and Alexander, 1995; McLaren et al., 1998; Sparks, Chapter 1). The processes that give rise to this time-dependent decrease in availability are known collectively as "the aging effect." Macroscopic observations of the aging effect are attributed to numerous molecular-scale phenomena, including pore and surface diffusion to sorption sites of higher affinity and long-term changes in bonded sorbate-sorbent structure (Figure 10.11). In the case of HOCs, sorption-desorption hysteresis is postulated to result from irreversible structural expansion and the creation of new micropores as a result of HOC molecules penetrating into the NOM sorbent phase. This leads to enhanced solid-phase affinity during subsequent desorption (Sander et al., 2006). Additionally, partial degradation of organic contaminants, as catalyzed by either extracellular enzymes or mineral surfaces, can lead to the formation of reactive intermediates that form covalent bonds with NOM (Dec and Bollag, 1997). These "bound residues" can be detected unambiguously only by using molecular probe methods such as ¹³C NMR spectroscopy (Hatcher et al., 1993).

Polymeric sorption complexes and surface precipitates of inorganic contaminants can result when high sorbate concentrations are contacted with natural geomedia for extended times. This can lead to slowly decreasing contaminant bioavailability. When such processes involve co-precipitation with major lithogenic elements such as Si, Al, and Fe, they tend to be strongly affected by the rates and trajectories of local mineral weathering. For example, under conditions of high metal loading and pH (>7) sorption of metals such as Co2+, Ni2+, and Zn2+ results in formation of mixed (e.g., Al-bearing) hydroxide surface precipitate phases that are of the layered double hydroxide (LDH) form (Scheidegger et al., 1996). Co-contaminant interactions can also be important to this process. For example, using a combination of soil column experiments and EXAFS spectroscopy, Voegelin and Kretzschmar (2005) demonstrated that the presence of Ni can enhance the immobilization of Zn by forming mixed Ni-Zn-LDH phases that are more resistant to dissolution than pure Zn-LDH precipitates. With further weathering time, these LDH phases are shown to transform to stable Si-bearing metal phyllosilicates, where the metal is sequestered in a form that is much less mobile and bioavailable (Scheckel et al., 2000).

Long-term sorption processes may also progressively diminish the bioavailability of cationic radionuclides (137Cs, 90Sr) because of silicate weathering reactions in soil media. This is particularly relevant in cases when radionuclides are released into the subsurface as part of an alkaline liquid waste that promotes native silicate dissolution. This has occurred, for example, at several Department of Energy sites, such as the Hanford site, that employed plutonium purification technologies (Zachara et al., 2007). Laboratory studies indicate that the dissolution of native silicate clays in the presence of caustic wastes gives rise to the precipitation of poorly crystalline aluminosilicate precipitates. These precipitates transform to more stable feldspathoid phases that then undergo "Ostwald ripening" in the liquid waste, which diminishes their subsequent dissolution kinetics when circumneutral pore waters are reintroduced (Qafoku et al., 2003; Chorover et al., 2008).

It should be noted, however, that prolonged residence time in geomedia is not a general solution for removing metals from bioavailable form. For example, although the application of biosolids to soil has the clear benefits of reducing landfill volumes and potentially increasing soil fertility in terms of NOM and nutrient content, there is also concern that sludge-bound metals will be subjected to introduction to the food chain (e.g., via plant uptake) as the organic matter, which serves as the principal metal-complexing component of the applied material, is slowly biodegraded (McBride, 2003). In other cases, metal sequestration is unfavorable thermodynamically, particularly in acidic soils, and contaminant remediation may require proactive intervention. Such approaches can nonetheless take advantage of geochemical phenomena. For example, a common remediation technique for Pb-contaminated soils involves the application of phosphate salts to promote the precipitation of sparingly soluble pyromorphite (Pb₅(PO₄)₃Cl) solids.

10.5 Microbial Intervention in Metal Cycling

Recent reviews have highlighted the importance of microbial diversity and its role in direct and indirect microbial mediation of biogeochemical and pollutant processing in the CZ (Newman and Banfield, 2002; Lovley, 2003). Examples of direct microbial mediation include assimilatory or dissimilatory reduction of metals [e.g., Fe(III), Mn(IV), Cu(II), U(VI)] and oxyanions (e.g., NO₃-, SO₄²⁻ AsO₄³⁻, CrO₄²⁻), the oxidative precipitation of metal hydrous oxides, and the biodegradation of organic contaminants. In all of these cases, the organisms derive some benefit from the reaction (energetic, nutritional, detoxification) that increases their chances of survival. These processes are typically very efficient, genetically controlled and thus subject to evolutionary change. Microbes also affect numerous abiotic reactions in an indirect manner. Typically these indirect effects are the consequence of a local change in the geochemical environment due to the presence of metabolic byproducts, and include, for example, the precipitation of carbonates, or dissolution of simple silicates, by proton-consuming metabolic activities such as photosynthesis or dissimilatory sulfate reduction. Biogenic Mn(IV) oxides such as acid birnessite, are another good example of indirect biological mediation in geochemical outcomes: they are believed to be the most abundant and highly reactive Mn oxide phases in the environment and when present can react with a wide range of organic and inorganic compounds and sequester a variety of metals (Tebo et al., 2004).

10.5.1 Microbially Mediated Redox Reactions

Largely because of continuous input of reduced C from autotrophic sources, biologically active soils undergo fluctuations in redox status as a result of hydrologic events or seasonal cycles and these have important implications for biogeochemical reactions. When previously oxic soils are subjected to depletion of dissolved or gaseous O2 because of soil pore filling with liquid water and associated gas diffusion limitations, heterotrophic microbes utilize alternative terminal electron accepting processes (TEAPs) in the respiration of organic matter. The sequence of TEAPs that occurs in waterlogged soil corresponds to the energetics of the reactions such that use of primary oxidants occurs in the order $O_{2(g)} \rightarrow NO_{3(aq)} \rightarrow Mn(IV)_{(s)} \rightarrow Fe(III)_{(s)} \rightarrow SO_{4(aq)} \rightarrow CO_{2(g)}$ While oxygen, nitrate, sulfate, and carbon dioxide are all present in the fluid phases, oxidized forms of manganese and iron are dominantly present in the solid phase because of their low aqueous solubility. In addition to the major elements O, C, N, S, Fe, and Mn, trace elements such as As, Se, Cr, Hg, U, and Mo also undergo speciation change as affected by biologically catalyzed redox reactions. The fluctuating redox conditions characteristic of soil systems have been studied experimentally by numerous investigators (McGeehan et al., 1998; Pett-Ridge et al., 2006; Thompson et al., 2006a,b). Redox fluctuations can be imposed by varying gas (e.g., $N_2/O_2/H_2$) partial pressures over various durations thereby forcing TEAPs to occur.

10.5.1.1 Iron Redox Cycling

The prevalence of iron in the Earth's crust and soils makes iron(III) reduction an especially important alternative TEAP in soils and sediments. Since iron (oxyhydr)oxides are sorbents for a wide range of nutrients and pollutants, this process also has implications for the sequestration and release of sorbed species. Ferric iron may serve as a dominant or exclusive terminal electron acceptor, or it may accompany fermentation as a supplementary terminal electron acceptor. Either case is considered dissimilatory iron reduction because Fe(III) is reduced biotically without being incorporated into specific cellular components (Ehrlich and Newman, 2009).

A wide variety of bacteria and archaea are capable of dissimilatory iron reduction, including both strictly anaerobic and facultative organisms. As a group, these organisms are capable of using dissimilatory Fe(III) reduction as a means to oxidize a wide range of organic molecules (e.g., ranging from acetate and lactate to palmitate and aromatic compounds), but some are unable to degrade the organic electron donor completely, often accumulating acetate (Lovley et al., 1989). The product of Fe(III) reduction is ferrous iron, and when released it can become adsorbed at the surface of the Fe(III) oxide undergoing reduction, interfering with microbial attack. Its removal from the iron oxide surface promotes the reduction of the oxide (Roden and Urrutia, 1999). In addition, Fe(II) is able to catalyze the structural transformation of Fe(III) minerals ferrihydrite and schwertmannite to more crystalline, thermodynamically stable forms, such as lepidocrocite and goethite (Pedersen et al., 2005; Burton et al., 2007). Iron isotope exchange experiments indicate that adsorbed Fe(II) induces electron transfer with mineral surface Fe(III) atoms, resulting in their reductive dissolution. The released Fe(III) then recrystallizes into an Fe(III) mineral species that is generally more crystalline and thermodynamically stable (Yee et al., 2006). In this way, microbial mediation can accelerate Ostwald ripening of mineral solids.

In a soil slurry experiment, Thompson et al. (2006b) subjected triplicate soil reactors of an Inceptisol to alternating one-week oxidation–reduction cycles shifting between E_h conditions either above (oxidizing) and below (reducing) equilibrium with ferrihydrite. Figure 10.12 shows the influence of such fluctuations on aqueous phase (a) pE or E_h , (b) dissolved Fe concentration, and (c) DOM concentration. The pH (not shown) and [Fe(II)] trends are inverse to those of E_h as expected for the reactions whereby dissimilatory Fe reduction (coupled to DOM oxidation) during the reduction cycles is followed by abiotic Fe(II) oxidation (coupled to O_2 reduction) during the oxidizing cycles. The data are consistent with the following reactions (shown using goethite as the Fe(III) solid undergoing dissolution-precipitation):

Reduction: FeOOH_(s) +
$${}^{1}\!\!{}_{4}\text{CH}_{2}\text{O}_{(aq)} + 2\text{H}_{(aq)}^{+}$$

 $\rightarrow \text{Fe}_{(aq)}^{-2+} + {}^{1}\!\!{}_{4}\text{CO}_{2(g)} + 2\text{H}_{2}\text{O}_{(l)}$ (10.6)

Oxidation:
$$Fe_{(aq)}^{2+} + \frac{1}{4}O_{2(aq)} + \frac{1}{2}H_2O_{(l)}$$

 $\rightarrow FeOOH_{(s)} + 2H_{(aq)}^{+}$ (10.7)

The data show that microbially mediated reductive dissolution of Fe(III) minerals can liberate organic matter from mineral-organic complexes. Using Mössbauer spectroscopy and selective chemical extractions, Thompson et al. (2006b) demonstrated that these redox oscillations in soils increase the iron oxide crystallinity, most likely as a result of the formation of aqueous Fe(II) under anoxic conditions and the subsequent onset of Fe(II)-catalyzed crystallization of Fe(III) minerals.

While Fe(III) occurs in a wide variety of secondary mineral types, it has been observed that microbially mediated Fe(III) reduction rates tend to increase with increasing specific surface area (Figure 10.13, Roden, 2008). Hence, ferrihydrite and nano-crystalline goethite tend to be utilized in preference to macro-crystalline goethite and hematite as electron acceptors for microbially mediated reductive dissolution. However, it is clear that Fe oxide mineralogy plays an important role, since different phases with comparable surface areas can show distinctly different Fe(III) reduction rates (Larsen and Postma, 2001). Reactivity can also be strongly impacted by wetdry cycling and surface "poisoning" of Fe(III) oxyhydroxides. A recent study of Fe(III) reduction rates using ascorbic acid as an electron donor showed that drying of ferrihydrite dramatically diminished its rate of reductive dissolution upon rewetting, whereas formation of ferrihydrite in the presence of dissolved silicon during crystallization significantly increased the reactivity of the dried and rewetted solid (Jones et al., 2009). The influence of Si on ferrihydrite reactivity is particularly intriguing, because it suggests that ferrihydrite formed in an active soil weathering environment is likely to be even more reactive than synthetic specimen minerals that have been most often used in experiments.

10.5.1.2 Contaminant Redox Reactions

Microbial metabolic (redox) processes in colonized soil and aquifer systems can alter the mobility of contaminants with dramatic

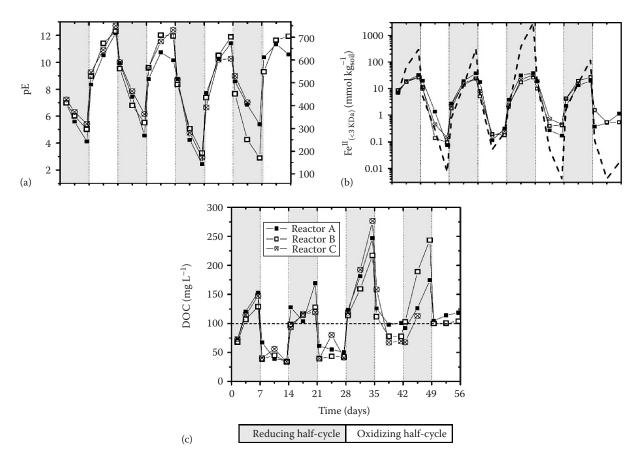

FIGURE 10.12 Iron redox cycling in triplicate Inceptisol soil slurry bioreactors show fluctuating soil redox status that can be imposed through $O_{2(g)}$ depletion during reducing cycles and its reintroduction during oxidizing cycles. Graph (a) shows pE (left axis) or E_h (mV, right axis). These fluctuations result in reductive dissolution of $Fe_{(aq)}^{2+}$ during the reducing half-cycles, and its precipitation as Fe(III) during oxidizing half-cycles (b). Dashed line in (b) shows equilibrium with ferrihydrite. Reductive dissolution of Fe solids results in the (c) dissolution and/or dispersion of organic carbon that was co-associated with aggregates containing Fe oxyhydroxide solids. (From Thompson, A., O.A. Chadwick, D.G. Rancourt, and J. Chorover. 2006b. Ironoxide crystallinity increases during soil redox oscillations. Geochim. Cosmochim. Acta 70:1710–1727. Copyright 2006, with permission from Elsevier.)

consequences for human and ecosystem health. For example, arsenic release to ground waters in the Bengal delta has been attributed to the microbial oxidation of DOM coupled to the reduction of sorbed As(V) to mobile As(III) (Islam et al., 2004). In this respect, it is noteworthy that, whereas it has been hypothesized that As dissolution is coupled to the reductive dissolution of the Fe(III) sorbents (e.g., iron oxyhydroxides), the study by Islam et al. (2004) shows that Fe and As release was decoupled in their experiments. The principal form of arsenic released to solution was As(III), and this occurred quite some time after Fe(III) bioreduction (Figure 10.14), indicating that As(V) was used as a terminal electron acceptor in respiration of DOM once the labile pools of Fe(III) had been depleted (Islam et al., 2004).

Conversely, microbial reduction of contaminant metals during respiration of organic matter can dramatically *reduce* contaminant bioavailability if the reduced species has a greater tendency to precipitate from solution, as is the case for the contaminant redox couples $\text{Cr}^{(\text{VI})}\text{O}_{4(aa)}^{2-7}/\text{Cr}^{(\text{III})}(\text{OH})_{3(s)}$ (Tokunaga et al., 2003a) and $\text{U}^{(\text{VI})}\text{O}_{2}^{2+}/\text{U}^{(\text{IV})}\text{O}_{2(s)}$ (Wilkins et al., 2006). Indeed, the "biomineralization" of contaminant metal species is an active area of research,

with clear application to remediation of contaminated soils and sediments (Lovley and Coates, 1997). However, given the dynamic nature of soil biogeochemical systems (e.g., fluctuations in redox status, as discussed above), the long-term stability of solid-phase bioreduction products remains a concern for systems that contain or can generate reactive metal oxidizing agents. For example, Tokunaga et al. (2007) have shown that Cr(III) solids formed by microbial bioreduction in the presence of labile organic carbon can be re-oxidized, most likely by Mn(III) or Mn(IV) containing solids. Manganese oxides are known to be effective oxidants of Cr(III), and they are capable of releasing significant hexavalent chromium into solution upon reaction (Fendorf et al., 1992; Oze et al., 2007). The fact that these solids are rapidly biosynthesized by Mn(II) oxidizing bacteria and fungi under oxic conditions (Tebo et al., 2004), suggests that their highly reactive surfaces may cycle in and out of prevalence in redox fluctuating environments, like biologically active soils, with potential dynamic impacts on Cr redox state.

Similar dynamics may affect the stability of biogenic $U^{(IV)}O_{2(s)}$. In a soil column study of U(VI) bioreduction stimulated by long-term dissolved OM influx, the persistence of Fe(III) solids

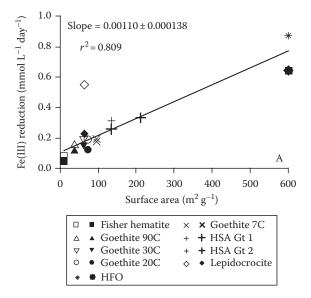

FIGURE 10.13 Initial rates of bacterial (*S. putrefaciens* and *G. sulfurreducens*) reduction of synthetic Fe(III) oxides as a function of oxide specific surface area. (With kind permission from Springer Science+Business Media: Roden, E.E. 2008. Microbial controls on geochemical kinetics 1: Fundamentals and case study on microbial Fe(III) oxide reduction, p. 335–415. *In* S.L. Brantley, J.D. Kubicki, and A.F. White (eds.) Kinetics of water-rock interaction. Springer, New York.)

as an electron acceptor led to re-oxidation and solubilization of biostabilized $UO_{2(s)}$ (Tokunaga et al., 2008). This occurred long after the depletion of both U(VI) and Mn(III and IV). Therefore, while bioreduction can be a very effective means for

partitioning contaminants out of mobile solution, it may also require a sustained input of reducing equivalents to maintain thermodynamic stability. In so far as soil biogeochemical processes impose dynamic shifts in environmental conditions, they can also alter the thermodynamic stability, bioavailability, and mobility of redox-active inorganic contaminants.

10.5.2 Biogeochemical Gradients

Biologically active soils have enormous capacity for chemical transformation of element species and organic chemicals. Mixing limitations—and therefore a high degree of spatial and temporal heterogeneity—give rise to steep geochemical gradients that promote reactive transformation of pollutants and nutrients along both biotic and abiotic pathways. Gradients arise temporally in response to input fluctuations such as rainfall events (Silver et al., 1999) and daily changes between photosynthetic and respiratory activity of the biota (Garcia-Pichel and Belnap, 1996). They also arise spatially because of local geochemical character and hydrologic state. A remarkable feature of soil systems is that steep geochemical gradients occur even across short distances (10⁻⁶-10⁻³ m) and timescales (Sexstone et al., 1985). Such gradients and their biogeochemical consequences have been particularly well documented by probing aqueous speciation of biological soil crusts in desert environments using micro-electrode techniques (Figure 10.15, Garcia-Pichel et al., 2003; Johnson et al., 2005, 2007). These data show the very large differences in molecular oxygen and nitrogen redox species that occur at the soil-atmosphere interface in desert soils subjected to an influx of water and substrate for microbial growth. Another particularly conspicuous case of such

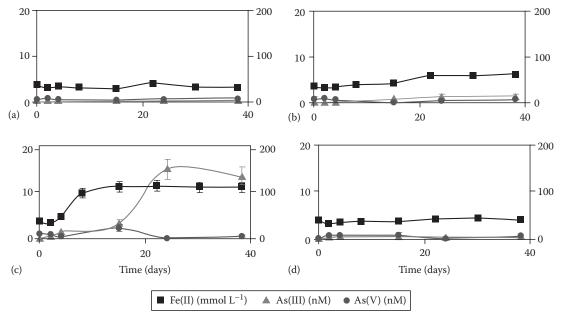

FIGURE 10.14 Reduction of Fe(III) and mobilization of arsenic in microcosms containing Bengali sediments incubated under a range of biogeochemical conditions: (a) oxic, (b) anoxic, (c) anoxic with 4 g L⁻¹ Na-acetate as a proxy for DOM, (d) abiotic control sediments with Na-acetate added, but autoclaved before incubation. Black squares, Fe(II); light gray triangles, As(III); gray circles, As(V). Each point and error bar represents the mean and standard deviation of three replicate experiments. (From Islam, F.S., A.G. Gault, C. Boothman, D.A. Polya, J.M. Charnock, D. Chatterjee, and J. R. Lloyd. 2004. Role of metal-reducing bacteria in arsenic release from Bengal delta sediments. Nature 430:68–71. With permission.)

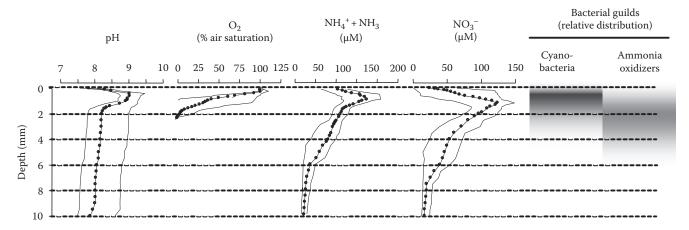

FIGURE 10.15 Vertical chemical gradients developing within the top cm of active (wet) biological soil crust communities as a consequence of microbial metabolic activity, as measured by microelectrodes. Photoautotrophic cyanobacteria close to the surface consume CO₂, driving pH up and creating an internal supply of O₂, which is quickly respired by heterotrophs to the point of anoxia some 2–3 mm below the surface. Leakage of cellular NH₃ produced by cyanobacteria during N₂-fixation, creates a very thin layer where both free NH₃ and O₂ are present, which in turn, constitutes a habitat for chemolithoautotrophic ammonia oxidizing bacteria. These then create a localized source of nitrate as a byproduct of their metabolism. This microscale clockwork constitutes the mechanistic basis for the fertilizing role of soil crust communities in arid lands at the landscape level. (From Chorover, J., R. Kretzschmar, F. Garcia-Pichel, and D.L. Sparks. 2007. Soil biogeochemical processes within the critical zone. Elements 3:321–326. With permission from Mineralogical Society of America. With original data from Garcia-Pichel, F., S.L. Johnson, D. Youngkin, and J. Belnap. 2003. Small-scale vertical distribution of bacterial biomass and diversity in biological soil crusts from arid lands in the Colorado Plateau. Microb. Ecol. 46:312–321; Johnson, S.L., C.R. Budinoff, J. Belnap, and F. Garcia-Pichel. 2005. Relevance of ammonium oxidation within biological soil crust communities. Environ. Microbiol. 7:1–12; Johnson, S.L., S. Neuer, and F. Garcia-Pichel. 2007. Export of nitrogenous compounds due to incomplete cycling within biological soil crusts of arid lands. Environ. Microbiol. 9:680–689.)

gradients is the well known "mottling" of soil color that results from proximal Fe reduction and oxidation processes that occur in adjacent regions of soil subjected to fluctuating redox status. These Fe "redoximorphic features" are indicative of soil systems that can support the metabolic activities of distinct bacterial species that gain energy from either Fe(III) reduction in anoxic microenvironments or Fe(II) oxidation in oxic or anoxic microenvironments that occur in close proximity (Weber et al., 2006).

To the extent that microbial species differ in their metabolic capacity to exploit geochemical gradients and capture energy, the heterogeneous nature of subsurface systems gives rise to a patchwork distribution of distinct microbial associations and geochemical functions from the regional scale ($10^{1}-10^{3}$ m) to that of particle aggregates ($10^{-3}-10^{-6}$ m) (Hunter et al., 1998). For example, the genetic structure of microbial communities has been shown to differ between the exterior and interior of soil aggregates, between various sized aggregates and bulk soil (Ranjard et al., 2000; Pankhurst et al., 2002), and it exhibits vertical patterns of segregation of functional types at the submillimeter scale in biological soil crusts (Figure 10.15) (Garcia-Pichel et al., 2003). Indeed, destruction of aggregate structure through land use change has been shown to diminish microbial diversity and patchiness at the soil aggregate scale (Lupwayi et al., 2001).

This spatial distribution also has implications for pollutant transformations. For example, Tokunaga et al. (2003b) found that the reduction of soluble Cr(VI) to insoluble Cr(III) occurred within the surface layer of soil aggregates where O_2 concentrations were limited by diffusion but where labile NOM concentrations were sufficient to promote high rates of microbial

respiration. Spatial distribution of microbially catalyzed redox reactions is also observed up to the field scale in subsurface sediments (Akob et al., 2007). One example is the distribution of redox potential from anoxic to suboxic to oxic as groundwater moves down gradient from an organic contaminant plume. Along this transect, one observes that organic matter decomposition is coupled to a sequence of TEAPs of progressively increasing energy yield as stronger oxidants become available. Common methods of sediment sampling and analysis that average over these geochemical gradients within aggregates and over larger spatial scales can erase important biogeochemical spatial relations necessary for understanding the processing that occurs in these environments (Tokunaga et al., 2003b).

It is now becoming increasingly clear that the processing of matter and energy in soil and aquifers does not only depend on the type of interacting components (biotic or abiotic) but also on their relative positions in space and the transport pathways between them. It is thus imperative that in future studies we strive to understand soils and the larger CZ on the basis of integrative "system architecture" rather than as mere compilations of compositional and distributional components acting independently of position (Hunter et al., 1998; Legout et al., 2005).

10.5.3 Biogeophysical Heterogeneities

In addition to the biogeochemical heterogeneity of interfaces described above, the CZ also exhibits extreme physical heterogeneity. Very wide pore size distributions lead to an associated distribution of water flow velocities and microenvironments. Studies

have found that pores are not distributed randomly, but rather that they are networked in ways that depend on the process of their formation. Near the soil surface, large pores can arise from the activities of roots, worms, or other soil organisms, whereas smaller pores within particle aggregates can form from abiotic aggregation processes, as well as root–microbe–soil interactions. Recent work using synchrotron microtomography and computational modeling suggests that microbes and plant roots "microengineer" their soil habitat by changing its porosity and spatial correlation, making it more porous, ordered, and aggregated in structure (Young and Crawford, 2004; Feeney et al., 2006). These studies also suggest that soil porosity and aggregate structure can undergo fluctuations in response to open system dynamics resulting from nutrient flux, biological activity, and microbial growth.

In macroporous systems, mass transfer is often approximated by a "dual porosity model" where solutes are transported advectively in macropores but also undergo diffusive transport into stagnant water associated with the microporous matrix or adsorbed to particle surfaces (Simunek et al., 2003). Hagedorn and Bundt (2002) have shown that such macropores in soils can persist as active preferential flow paths for several decades. In some clay-rich soils, shrinking and swelling can also lead to a pronounced aggregation of the soil and the formation of large cracks. At greater depth penetration into bedrock, large pores can result from rock fractures and physical and chemical weathering. The connectivity and length of these large pores have a major influence on the nature and amount of interface contacted by water, solutes, and colloids as they traverse the CZ (Allaire-Leung et al., 2000). Macropores serve as preferential flow paths where water, nutrients, and pollutants travel much faster than they do in a homogeneous medium of the same total porosity (Reedy et al., 1996). While this diminishes the extent of interfacial contact and reaction with the soil matrix, it also can enrich macropore surfaces with sorbing pollutants (Hagedorn and Bundt, 2002). Similarly, enhanced delivery of nutrients and or metabolic substrates for bacteria may promote their preferential growth on walls of large pores. In extreme cases, such as the disposal of large amounts of organic waste, ensuing enhancement of heterotrophic bacterial growth can lead to pore clogging and decreased hydraulic conductivity (Baveye et al., 1998).

Superimposed on the particle- to pedon-scale distribution of reactive interfaces is the variability in geochemical environment that occurs at the landscape scale because of hydrologic partitioning through geomorphically variable terrain. Landform structure forces migrating water to sample distinct geochemical environments along its transmission through the Earth's surface. One example is the movement of precipitation through oxic weathering environments on hillslope uplands prior to convergence on an organic-rich riparian zone at lower elevation where reducing conditions may predominate. Geomorphic structure then feeds back to affect the nature of interfaces formed at different locations in the landscape. For example, whereas Fe(III) oxyhydroxide formation may be favored in the oxic, upland weathering environment, such phases may become unstable relative to dissolved Fe(II) in

the riparian reducing environment. Corresponding "hotspots" of biological activity may also favor local losses of N through denitrification under anoxia (Schade et al., 2002).

10.6 Conclusions and Future Prospects

The transport and fate of nutrients and pollutants in the CZ depend on physical and biogeochemical interactions among living and non-living soil components. In this chapter, we have emphasized the fact that these components do not create a stationary matrix for such interactions. Conversely, soils are a highly dynamic system where feedbacks between biotic and abiotic components create a weathering environment where mineral and organic transformations alter the form and bioavailability of both essential and toxic species.

Significant advances have been made in recent years in the subdisciplines of soil and earth sciences that have enabled much better characterization of these systems from catchment to molecular scales. However, our understanding of key processes remains incomplete, particularly for those phenomena that involve process coupling across the subdisciplines of organic and inorganic soil chemistry, biology, and hydrology. Specifically, research is needed to better resolve (1) the precise mechanisms whereby plants and microbes affect chemical denudation versus mineral transformation rates; (2) the biogeochemical processes leading to the formation of the continuum of mineral-organic complexes and their higher order micro- to macro-aggregate structures; (3) the "architecture" of these complexes, including the nature of bonds that are formed at mineral-organic interfaces, and the types of intermolecular associations that lead to further "layering" above the mineral surface; (4) the role of these complexes in affecting the surface complexation and sorptive retention of nutrients and pollutants, and (5) the kinetic and thermodynamic stability of bio-remediation products, particularly solid phase products of contaminant (e.g., U(VI) and Cr(VI)) bioreduction.

Acknowledgments

Several concepts and ideas in this chapter grew out of an earlier paper that was co-authored by R. Kretzschmar, D. L. Sparks, and F. Garcia-Pichel (Chorover et al., 2007). I am grateful to these individuals in particular for fruitful discussions and interactions over that earlier work. Support for preparation of this manuscript was provided by the National Science Foundation, NSF EAR 0724958.

16	Nutrient Interactions in Soil Fertility and Plant Nutrition William L. Pan	16-1

HE BIOLOGICAL, CHEMICAL, AND PHYSICAL FACTORS that control the availability of plant essential and beneficial nutrients as well as potentially phytotoxic and zootoxic microelements are reviewed in this part. Nutrient and elemental availability is important not only as it affects crop plant productivity, but as it determines the potential movement of nutrients outside the boundaries of the crop field and their impact on air and water resources and native ecosystems. The complexity of soil acidity and nutrient interactions as they affect plant uptake and utilization of nutrients

are also elaborated in this part. The use of fertilizer nutrients by crop plants, as it is affected by fertilizer material and application timing and placement, are discussed with regard to nutrient mobility and reaction with the soil. Ultimately, the continuum of soil–fertilizer–plant–climate interactions determines the efficiency of nutrient and water use. The economically and environmentally sound management of nutrients and toxic elements is facilitated by accurate soil and plant tissue testing methods that account for all these factors impacting availability.

In addition to C, H, and O, at least 14 mineral elements accumulated by root uptake from the soil are considered essential for most plants (N, P, K, Ca, Mg, S, Cu, Mn, Fe, B, Ni, Mo, Cl, and Zn). N, P, and K are often classified as "major" or "macro" nutrients, because they are frequently deficient in agricultural production, and when deficient they can have substantial impact on crop productivity. Although N and P are accumulated in large quantities by plants, the uptake of P is considerably less, on par with the "secondary" nutrients, Ca, Mg, and S. Silicon may not be essential to complete the life cycle of most plants, but its uptake by some plants, like

rice and sugarcane, far exceeds that of N or K, and its impact on productivity of these crops can be great. "Minor" or "trace" elements include both biologically essential "micro" nutrients (Cu, Mn, Fe, B, Ni, Mo, Cl, and Zn) and nonessential elements (e.g., Al, Pb, Cd, and Hg). Plant tissue micronutrient sufficiency levels are quite low; however, at high levels of availability, both essential and nonessential elements can become toxic to plants or animals.

The principles of soil fertility and plant nutrition affecting the growth of plants and impacting the environment are discussed in the following six chapters.

11.1 Bioavailability of Nitrogen

James J. Camberato

11.1.1 Introduction

The focus of this chapter is to illustrate how the fundamental transformations and transport of nitrogen (N) in the soil alter its bioavailability and impact plant productivity and environmental quality. Nutrient bioavailability or availability can be defined in many ways. Of the 10 definitions described by Blackmer (1999), that of Peck and Soltanpour (1990, p. 4) is most appropriate to this chapter: "By plant-available nutrient, one usually means the chemical form or forms of an essential plant nutrient in the soil whose variation in amount is reflected in variations in plant growth and yield."

The transient nature of N in soil and the large quantity accumulated by plants both contribute to the frequent occurrence

of N deficiency in nonlegumes. Maximizing N bioavailability from indigenous soil N and added N (fertilizer, manure, legume residues, etc.) to optimize the yield of crop plants was the initial impetus to understanding N bioavailability. Considerable study of N transformations and transport determined that the processes of mineralization and immobilization, nitrification and denitrification, volatilization, and leaching control N bioavailability. With time, it was realized that N losses from agricultural systems via leaching, denitrification, and ammonia (NH₃) volatilization impacted surface and ground water, atmosphere, and noncultivated ecosystems; and much emphasis was then placed on quantifying and understanding these effects as well.

11.1.2 Nitrogen Cycle

Nitrogen bioavailability to plants is dynamic—the result of several interrelated microbial, chemical, and physical processes in

soils, which are contingent upon the nature of the soil as well as temperature, moisture, energy, and other factors. The connectivity of these processes is often displayed as "The Nitrogen Cycle" (Section 27.1 of *Handbook of Soil Sciences: Properties and Processes*).

Nitrogen inputs to soils include N fixation, atmospheric deposition, and purposeful nutrient application (fertilizers, manures, etc.). Although dinitrogen gas (N_2) comprises $\approx 80\%$ of the atmosphere, it can only be utilized by a few species of free-living bacteria and blue–green algae, and specialized N-fixing bacteria that form symbiotic relationships with leguminous plants (Section 27.1 of *Handbook of Soil Sciences: Properties and Processes*). Historically, the majority of reactive N (N molecules other than N_2) arose from microbial N fixation, until the recent (geologically speaking) development of the Haber–Bosch fertilizer manufacturing process (Galloway and Cowling, 2002; Mosier, 2002). The only other natural processes contributing significantly to the oxidative fixation of N_2 are lightning (Noxon, 1976; Liaw et al., 1990), fire, and volcanic activity (Bandy et al., 1982; Huebert et al., 1999).

With the industrial revolution came an increase in atmospheric deposition of reactive N, mostly due to the burning of N-containing substances. More than 90% of the N in organic residues is lost to the atmosphere with burning (Heard et al., 2006), most as NO_x (nitric oxide [NO] and nitrogen dioxide [NO₂]), nitrous oxide (N₂O), NH₃, hydrogen cyanide (HCN), and higher N-compounds (Lobert et al., 1990). On a global scale, atmospheric N deposition from anthropogenic sources has exceeded that from natural sources since the mid-twentieth century (Galloway, 2001) and was recently estimated to be about fourfold that from natural sources (Fowler et al., 2004). Smil (1999) reported wet deposition of 1 kg N ha-1 in the United States, west of the Mississippi, 7 kg N ha⁻¹ in the coastal Northeast, and as much as 20 kg N ha-1 in the Netherlands, northeastern France, and southern England. Although the deposition of reactive N might be viewed positively in its contribution to plant productivity, atmospheric N deposition also contributes to soil and water acidification (Galloway, 2001; Rodhe et al., 2002), eutrophication of surface waters (Fisher and Oppenheimer, 1991; Bergström and Jansson, 2006), and decreased ecosystem diversity (Bobbink et al., 1998; Lee and Caporn, 1998). Additional beneficial and detrimental effects of reactive N in the environment are overviewed in Section 27.5 of Handbook of Soil Sciences: Properties and Processes and Galloway and Cowling (2002).

11.1.3 Nitrogen an Essential Plant Nutrient

"Nitrogen is without doubt the most spectacular of all essential nutrients in its effect on plant growth" (Olson and Kurtz, 1982, p. 568). Plant growth responses to increasing N bioavailability are more frequent and larger than to any other essential nutrient. Viets eloquently stated, "No one can claim that N is more essential than any of the other 15 elements known to be needed for higher plants, but on the basis of relative number of atoms

needed, N is at the top of the list of those that come from soil or fertilizers," (Viets, 1965, pp. 503–504). Nitrogen is a component of nucleic acids (RNA and DNA), amino acids (proteins and enzymes), and chlorophyll. Detailed information on the role of N in plant nutrition can be obtained from Lea and Morot-Gaudry (2001) and Amâncio and Stulen (2004).

Plant tissue sufficiency concentrations of N differ among plant species and plant parts, ranging from ≈20 to $50\,\mathrm{g}$ N kg⁻¹ as reported by Olson and Kurtz (1982). Legumes have higher tissue N concentration than nonlegumes, >40 versus <40 g kg⁻¹. Most plant N is in the organic or reduced form, although nitrate (NO₃⁻) will accumulate to some extent in some situations (Grunes and Allaway, 1985, pp. 594–597). Aboveground N accumulation may exceed several hundred kilograms per hectare in productive environments, but in most environments N bioavailability limits the growth of nonleguminous plants.

Inadequate N bioavailability reduces overall plant growth and often results in chlorosis (yellowing) of plant tissues, a result of reduced chlorophyll content. Since N is highly mobile in the plant, chlorosis and necrosis of older plant tissues precedes the chlorosis of younger tissues, as N is translocated from older to younger plant parts. Descriptions and photographs of N deficiency on many important grain, sugar, oilseed, vegetable, and fruit crops as well as turfgrasses can be obtained from Bennett (1993). Excess N can also have detrimental effects on plants; including delayed flowering, reduced fruit set, and increased lodging. Excess N can impair the utilization and quality of crop plants, including poor wear tolerance of turfgrasses, reduced sugar concentration of sugar beets, lower tobacco leaf quality, and excessive NO₃- content of vegetables and forages.

11.1.3.1 Nitrogen Uptake by Plants and Microorganisms

Nitrogen is accumulated by plants from the soil as the anion NO₃⁻ and the cation NH₄⁺. Most plants readily accumulate both inorganic forms, with perhaps the exception of blueberry (Vaccinium corymbosum L.; Claussen and Lenz, 1999) and cranberry (V. macrocarpon Ait.; Greidanus et al., 1972), which often demonstrate a strong preference for NH₄⁺. Some nondomesticated plants may have a preference for NH₄⁺ or NO₃-, depending on their adaptation to soil pH and the predominant form of N naturally occurring in the soil. Species adapted to acid soil environments may prefer NH₄⁺ (Atkinson, 1985); the most prevalent form of N in acid soil, whereas less acid-tolerant species may prefer NO₃- (Gigon and Rorison, 1972). However, many nondomesticated plants, as do crop plants, grow best on a mixture of NH₄⁺ and NO₃⁻ (Rorison, 1985; Falkengren-Grerup, 1995). Nitrogen accumulation by plants can be rapid. Bowman et al. (1989) calculated a rate of ≈35 kg N ha⁻¹ day⁻¹ for field-grown, moderately N-deficient Kentucky bluegrass (*Poa pratensis* L.). In Maize (*Zea mays* L.), N accumulation rates peaked between 5 and 15 kg N ha-1 day-1 (Karlen et al., 1987).

Heterotrophic microorganisms accumulate NH₄⁺ over NO₃⁻ when both are present (Jansson et al., 1955; Wickramasinghe

et al., 1985; Rice and Tiedje, 1989), but will readily accumulate NO_3^- if it is the only form present (Davidson et al., 1990; Recous et al., 1990). Microorganisms are more competitive for N than plants in the short term. In 24h 15 N uptake studies conducted in a Mollic Haploxeralf, annual grassland plants accumulated NO_3^- and NH_4^+ at rates of 0.6 and 1.0 kg N ha $^{-1}$ day $^{-1}$, respectively (average for April and February measures), whereas microbial uptake was two- to fivefold higher at 1.1 and 5.3 kg N ha $^{-1}$ day $^{-1}$ (Jackson et al., 1989).

11.1.3.2 Ammonium and Nitrate Nutritional Effects on Plant Growth and Development

Many greenhouse, growth chamber, and hydroponics experiments demonstrated greater N uptake and/or growth of several crop species when provided both NO₃⁻ and NH₄⁺, compared to a preponderance of one N form over the other (Schrader et al., 1972). Since NO₃⁻ is the predominant form of N available to plants in most cultivated soils, a nitrification inhibitor is often used to increase the proportion of total N that is in the NH₄+ form. Crops that respond favorably to mixed N nutrition or enhanced NH₄+ supply include barley (Hordeum vulgare L.; Leyshon et al., 1980); sorghum (Sorghum bicolor (L.) Moench; Camberato and Bock, 1989); wheat (Triticum aestivum L.; Camberato and Bock, 1990); maize (Below and Gentry, 1992); and Italian ryegrass (Lolium multiflorum Lam.; Alderman and Streeter, 1997). Unfortunately, this advantage of enhanced NH₄+ supply has only infrequently been reported in field grown plants (Smiciklas and Below, 1992). Difficulty inhibiting nitrification to enhance NH₄+ supply or positional availability of NH₄+ may minimize the advantage to mixed N nutrition in field situations (Bock, 1986). Plants grown in soils where most of the N is derived from soil organic matter and plant residues and in acid or cold soils where nitrification is slowed may accumulate significant amounts of N in the NH₄+ form without the aid of an artificial nitrification inhibitor. Otherwise, soils have little propensity to accumulate or store bioavailable NH₄+-N (Chang et al., 1991; Muñoz et al., 2003).

11.1.4 Nitrogen Transformations Affecting Nitrogen Availability

Nitrogen bioavailability to nonleguminous plants is predicated in the presence of $\mathrm{NH_4^+}$ and $\mathrm{NO_3^-}$ for root uptake. Thus, indigenous soil N, applied organic N, uric acid, urea, and other N-containing substances are only available to the plant after they are mineralized to $\mathrm{NH_4^+}$ and $\mathrm{NO_3^-}$. Nitrogen mineralization and immobilization (the microbial transfer of inorganic N to organic N) are discussed in detail in Section 27.2 of *Handbook of Soil Sciences: Properties and Processes*. Although $\mathrm{NH_4^+}$ is subject to conversion to $\mathrm{NH_3}$ in a high pH environment and volatilization to the atmosphere if on the soil surface, the loss of $\mathrm{NH_4^+}$ from the soil is considerably less overall than the loss of $\mathrm{NO_3^-}$. Unfortunately, the nitrification of $\mathrm{NH_4^+}$ to $\mathrm{NO_3^-}$ (see Section 27.3 of *Handbook of Soil Sciences: Properties and Processes* for details) occurs readily in most soils and the subsequent loss of $\mathrm{NO_3^-}$ by leaching and denitrification substantially reduces N bioavailability.

11.1.4.1 Nitrogen Mineralization

The rate and extent of N mineralization determines the bioavailability of organic N sources, most importantly soil organic matter, crop residues, manures, and by-products of municipal waste treatment and industrial processes.

11.1.4.1.1 Soil Organic Matter

Stevenson (1982) reported that >90% of the N in soils is in the organic form. Organic N in the plowed layer of mineral soils ranges from 0.8 to 4.0 g N kg⁻¹ (Bremner, 1965, p. 96) representing 1800-9000 kg N ha-1. Thus, a 2% mineralization rate would provide 36-180 kg inorganic-N ha-1, potentially a significant percentage of crop N accumulation. Cassman et al. (2002) determined indigenous N from maize uptake in 55 field experiments in the North-Central United States to typically range between 80 and 240 kg N ha-1, with most providing between 100 and 140 kg N ha⁻¹. Predicting N bioavailability from soil organic N is important to increase the efficient use of fertilizer and added N and to decrease N losses to the environment (Cassman et al., 2002; Mulvaney et al., 2005). The importance of moisture and temperature (Stanford and Epstein, 1974; Kladivko and Keeney, 1987) and pH (Cornfield, 1952; Dancer et al., 1973; Olness, 1999) on N mineralization are well established. Unfortunately, laboratory tests of N mineralization have largely been unsuccessful (Griffin, 2008) in predicting N mineralization in the field, likely because most do not account for the impact of varying temperature and/or moisture in the field on N mineralization. Honeycutt et al. (1991) and Griffin and Honeycutt (2000) improved the incubation-based prediction of N mineralization from soil organic N, fertilizer, crop residue, sludge, and manure by including cumulative thermal units into equations based on soil properties and moisture.

11.1.4.1.2 Crop Rotation and Residue Effects on Nitrogen Bioavailability

Much effort has been placed on determining the cause of lower yield and higher N requirement in continuous maize compared to maize grown after soybean (Glycine max L.). Nitrogen availability is an important factor, although many other factors also contribute. Nitrogen uptake by maize grown after soybean in Wisconsin was 51 kg N ha⁻¹, greater than maize grown after maize on two silt loams, but no different in a sandy soil (Bundy et al., 1993). Nitrogen uptake of a second cereal crop grown 2 years after soybean was reduced to 36 kg N ha⁻¹ (Vanotti and Bundy, 1995). The authors proffered that the second year reduction in N bioavailability was due to soybean removing more N from the soil than was fixed symbiotically as described by Heichel and Barnes (1984) and others (David et al., 1997; Jaynes et al., 2001). The yield benefit of maize grown after soybean, compared to maize grown after maize, was the same whether the soybean was nodulating or nonnodulating, and was not eliminated by the application of fertilizer N to a silt loam in Wisconsin (Maloney et al., 1999). These findings suggest that the "rotation effect" was not likely a result of N provided directly by the soybean crop, but an enhancement in the maize plant's ability to accumulate and utilize N. However, Gentry et al. (2001), using a similar experimental approach including nodulating and nonnodulating soybean, had a different conclusion. The "rotation effect" was due both to a decrease in N mineralization in continuous maize and to an increase in soil N arising from symbiotic fixation in maize after soybean.

Alternatively, it has been suggested that the effects of crop residues on N bioavailability may arise from their effect on soil temperature. Normal amounts of corn residue or simulated residue lowered soil temperature 0.7°C-1.7°C and resulted in 32 kg ha-1 less N than when residues were removed (Andraski and Bundy, 2008). Since the simulated residue (polypropylene snow fence) had a similar effect on soil temperature and N availability as corn stover, it was concluded that temperature, not microbial immobilization, had altered N bioavailability. This seems plausible since only 3-5kg ha⁻¹ of soybean residue-derived N was taken up by maize grown the following season on two Mollisols in Kansas, even though 144-155 kg N ha-1 more N fertilizer had to be supplied to maize grown after maize to achieve the same yield as maize after soybean (Omay et al., 1998). Crookston et al. (1991) pontificated that the "rotation effect" was "a somewhat fickle and elusive phenomenon" and was "easier to exploit ... than to explain." Twenty years later this statement is still true.

11.1.4.1.3 Cover Crop Effects on Nitrogen Bioavailability

Legumes grown as cover crops differ in N fixation and residual N accumulation (Heichel and Barnes, 1984). Conditions affecting the growth of a cover crop, such as moisture and temperature, also affect its N fixation and recovery of residual N, thereby affecting the potential N contribution to the subsequent crop. The rate and extent of N mineralization from the cover crops determine the bioavailability to the following crop, which is influenced by the composition of the cover crop, placement on or incorporation in the soil, moisture, and temperature. Plant tissue with high C:N and high concentrations of lignin, cellulose, and hemicelluloses decompose and release N slower than plants with lower levels of these constituents (Wagger et al., 1998).

Legumes can fix considerable amounts of N that are significant when compared to the uptake of the subsequent cereal crop. For example, in Delaware, hairy vetch (Vicia villosa Roth.) and crimson clover (Trifolium incarnatum L.) grown in combination with spring oats (Avena sativa L.) or cereal rye (Secale cereale L.) accumulated ≈117 kg N ha⁻¹ more N in cover crop roots and shoots than when either cereal was grown alone (≈55 kg N ha⁻¹) (Mitchell and Teel, 1977). An average of 90% of the cover crop N was in the top growth and about 33% of the N was released to the following maize crop. Similarly in North Carolina, crimson clover and hairy vetch, compared to a fallow treatment, increased N recovery by the subsequent maize crop ≈42 kg N ha⁻¹; equivalent to about 33% of the aboveground N content of the cover crops (Wagger, 1989a). Cereal rye, in comparison to legume cover crops, reduced N recovery by about 25 kg N ha-1 compared to fallow—likely arising from the high C:N of the rye (≈35:1; Wagger, 1989b) and N immobilization. Hairy vetch, big flower vetch (Vicia grandiflora W. Koch), and crimson clover

grown as winter cover crops in Kentucky accumulated 173, 24, and 20 kg N ha⁻¹ more aboveground plant N than cereal rye (36 kg N ha⁻¹), respectively (Ebelhar et al., 1984). Poor growing conditions, including low rainfall, reduce N accumulation. Four cover crop systems grown in the Brazilian Cerrados contributed 25–64 kg N ha⁻¹ to the following maize crop in one season, but had no effect in the second season in which cover crop growth and N uptake were reduced by dry weather (Maltas et al., 2009).

Date of planting (growing season length), killing date, and moisture affect N fixation and N recovery of cover crops. A late August planted wheat-hairy vetch mixture grown 30 km south of Vancouver, British Columbia produced 126 kg N ha⁻¹, whereas the same mixture planted 4 weeks later produced only 70 kg N ha⁻¹ (Odhiambo and Bomke, 2001). Many researchers have focused studies on the impact of kill date on cover crop N accumulation (Wagger, 1989a, 1989b; Clark et al., 1994, 1997; Odhiambo and Bomke, 2001; Sainju and Singh, 2001). The longer the cover crop is allowed to grow, the greater the amount of N that is fixed or recovered from the soil. Hairy vetch and a vetch-cereal rye mixture accumulated ≈2 kg N ha⁻¹ day⁻¹ in the aboveground biomass form late March until early May in Maryland (Clark et al., 1997).

Temperature, moisture, and placement of cover crop residues affect N contribution of the cover crop to the subsequent main crop. For several cover crops, faster N mineralization occurred in the first year of a 2 year study, due to higher rainfall (79 versus 15 mm) and higher mean air temperature (29°C versus 25°C) in the first 4 weeks of residue decomposition in North Carolina (Ranells and Wagger, 1996). Nearly complete N release from the hairy vetch cover crop occurred twice as fast in year 1 than year 2, 8 versus 16 weeks. Incorporating legume cover crop residue into a *Typic Paleudalf* in Kentucky increased the rate and extent of N release to the following crop (Varco et al., 1989). Maize recovered 31 kg ha⁻¹ more N when hairy vetch was incorporated into the soil compared to when left on the soil surface, 32% versus 20% of the residue N content, respectively.

Nonlegume cover crops can be effective at recovering residual N from a previous crop or a post-growing season manure application. Nitrogen accumulation and subsequent release to the following crop determine bioavailability and environmental impact. In an irrigated *Xeric Torripsamment* sand in eastern Washington, about 29% of the 92–142 kg N ha⁻¹, captured by a mustard (*Brassica hirta* Moench) cover crop from fertilizer applied to a winter wheat-sweet corn-sweet corn rotation was recovered by the following potato (*Solanum tuberosum* L.) crop (Collins et al., 2007).

Cover crops can increase N bioavailability by reducing percolation losses (Weinert et al., 2002) as well as by recovering residual N. An estimated 50% of the 9 cm of winter rainfall was used by cover crops grown on a *Xeric Torripsamment* in the Columbia Plateau of central Washington. Thus, soil mineral N was reduced by 155 kg N ha⁻¹ to a depth of 180 cm by cereal rye, wheat, or rapeseed (*B. napus* L.). However, winter water use by cover crops can sometimes reduce yield and N recovery by the subsequent crop, particularly in semiarid regions (Unger and Vigil, 1998). Bioavailability of cover crop N can be assessed by aboveground N accumulation, with the PSNT soil test for NO₃⁻ or NO₃⁻ and NH₄⁺ (Vaughan and Evanylo, 1999), or growing degree day predictive methods (Schomberg and Endale, 2004).

11.1.4.1.4 Nitrogen Bioavailability from Animal Manure and Organic N Sources

The term "animal manure" is used to refer to the array of complex substances arising from animal feces, urine, bedding, unused ration, water, medications, and growth promoters. Organic substances used as N sources for crop plants include by-products from vegetable, meat, oilseed, starch and sugar processing, municipal waste treatment (sewage sludge or biosolids), paper manufacturing, and other processes. A thorough discussion of these by-products can be found in Power and Dick (2000). This section will concentrate on N bioavailability from animal manure, although the same principles apply to other organic N sources. Nitrogen forms in manure include NO₃-, NH₄+, NH₃, urea, uric acid, and complex organic N compounds. Managing and predicting N bioavailability from manures is more difficult than that from inorganic fertilizer because of the variable composition of these materials and practical considerations that foster less than optimum timing and placement. The transformations of these compounds as affected by application method, timing, soil cation exchange and buffer capacity, and weather determine N bioavailability, but are difficult to predict. Bioavailability estimates for manures generally include availability factors for N that consider inorganic N loss (primarily NH3 volatilization and NO₃- leaching), based on application method and timing and an estimate of organic N mineralization. Nitrogen bioavailability from manure may also be represented in terms of "fertilizer replacement value" or "fertilizer equivalency," which does not take into account N loss that both fertilizer and manure N would be subjected to equally.

Manure N availability algorithms for making manure application rate recommendations for 34 states were reviewed and programmed by Joern et al. (2009). They found that 27 different variables were used to determine plant-available manure N and that for any single state 5 to 12 variables are needed to make this determination. While the number of variables required is indeed large, once the manure source is determined, 12 states use only one factor (e.g., total manure N) and 15 states use only two factors (e.g., total manure N and application method) to determine plant-available manure N. All but one state include method of application to determine plant-available manure N; however, only 13 out of 34 states use month of application to determine manure N availability.

Pratt et al. (1973) developed the "decay series" concept to represent manure N bioavailability over multiple growing seasons. The yearly rates of N mineralization in a decay series are given as the fraction of total N (year 1) or residual N (year 2 and beyond) mineralized. For example, if manure were applied containing 100 kg N ha $^{-1}$, the decay series 0.35, 0.15, 0.10, and 0.05 would predict mineralized N of 35 kg ha $^{-1}$ in year 1 (0.35 \times 100 kg N ha $^{-1}$), 9.8 kg ha $^{-1}$ in year 2 [0.15 \times (100 - 35 kg N ha $^{-1}$)], 5.5 kg ha $^{-1}$

in year 3 [0.10 \times (100 - 35 - 9.8 kg N ha⁻¹)], and 2.5 kg N ha⁻¹ in year 4 $[0.05 \times (100 - 35 - 9.8 - 5.5 \text{ kg N ha}^{-1})]$. Nitrogen bioavailability from successive annual applications of manure would include N mineralized from previous seasons as well as the current growing season. Thus, if manure containing 100 kg N ha-1 were applied annually, N bioavailability in year 4 of the previous example would be $52.8 \text{ kg ha}^{-1} (35 + 9.8 + 5.5 + 2.5 \text{ kg N ha}^{-1})$. The term "mineralized" was used by Pratt et al. (1973) to represent inorganic N released from urea and uric acid as well as slowly mineralizable organic N. Although this concept was originally put forth to estimate actual mineralization, the author's first experimentally based decay series, 0.40, 0.25, 0.06 from a field trial in the Coachella Valley, California, was based on fertilizer equivalency. Not surprisingly, decay series were found to be soil dependent. Dairy manure N bioavailability determined in a 5 year Vermont study was lower on a somewhat poorly drained clay soil (decay series-0.35, 0.15, 0.10, 0.075, and 0.05) than on a well-drained loam soil (decay series-0.60, 0.15, 0.10, 0.075, and 0.05), perhaps due to denitrification losses in the year of application (Magdoff, 1978).

Plant-available N in poultry litter was estimated in incubation studies to be approximately 80% of the inorganic N and 60% of the organic N contents and this provided a reasonable estimate of N bioavailability in two field experiments with maize, conducted in sandy loam Ultisols in Delaware (Bitzer and Sims, 1988). Nitrogen recovered in the second growing season from the 280 kg organic N ha⁻¹ added at the highest rate of poultry manure was equivalent to only 31 and 16 kg N ha⁻¹ fertilizer N, 11% and 6% of the organic N applied. Camberato and Frederick (1994) found no difference in residual N from poultry manure and fertilizer N applied at comparable N rates. High N availability shortly after poultry manure application and little residual value suggest that poultry manure application timing should be similar to that recommended for inorganic fertilizer to avoid leaching and denitrification losses.

Swine manure is often handled as a slurry or liquid from a lagoon. In this form 60%-80% of the total N content is in the NH₃/NH₄⁺ forms (Mikkelsen, 1997). Thus, NH₃ volatilization from surface applications affects bioavailability. Only 40% of the total N content of surface-applied liquid swine manure slurry is considered available in comparison to 70%, when incorporated. Rapid conversion of NH₄⁺ to NO₃⁻ and subsequent leaching and denitrification losses would be similar to those incurred with NH₄⁺ fertilizers. Swine manure lagoon sludges have a higher organic N content (75%), thus predicting that organic N mineralization is a main determinant of bioavailability.

Dairy manure has a higher C:N ratio and more organic N than poultry or swine manure. Net nitrification and immobilization from nine dairy manures was more accurately predicted by considering the impact of manure C or neutral detergent fiber on N transformations (Griffin et al., 2005). The fertilizer N equivalency of dairy manure organic N was determined from maize N accumulation in New York to be 21%, 9%, 3%, 3%, and 2% of the original organic N content in years 1–5 after application, respectively (Klausner et al., 1994).

11.1.5 Factors Reducing N Bioavailability

11.1.5.1 Nitrogen Immobilization

Nitrogen can be added to the soil, remain in the rootzone, yet be unavailable to the crop. Immobilization of inorganic N by microorganisms decomposing high C:N crop residues (>20–30:1), such as maize, oat, or wheat stover or other organic materials can render substantial quantities of inorganic N unavailable for periods of time (Alexander, 1977). Substances such as sawdust or other wood-based by-products can have an even greater effect on N bioavailability than crop residues. For example, a papermaking sludge with a C:N ratio of 480:1 immobilized soil N for at least 250 days when added at 267 g sludge kg $^{-1}$ soil (Zibilske, 1987). Ammonium is preferentially used by heterotrophic microflora, but NO_3^- is also immobilized in the absence of NH_4^+ (Recous et al., 1990).

11.1.5.2 Conversion of Ammonium to Nitrate Increases the Potential for Nitrogen Loss

Losses of NH₄⁺-N from soil are generally small but NO₃⁻-N can be lost in large quantities by leaching and denitrification. Thus, nitrification, the conversion of NH₄⁺ to NO₃⁻ by *Nitrosomonas* and *Nitrobacter* (see Section 27.3 of *Handbook of Soil Sciences: Properties and Processes*), is a critical factor that determines N bioavailability in many situations. Many factors affect nitrification rate, including temperature, pH, and soil type.

In laboratory incubations the nitrification rates of four soils increased with increased temperature from near 0°C to 27°C or 35°C, dependent on soil type (Frederick, 1956). The rate of nitrification is increased by increased temperature, but can proceed at relatively high rates with low temperatures in some soils. For example, equal nitrification rates occurred in a clay loam Ultisol incubated at 32°C or 8°C, but only after a 6 week lag period at the lower temperature (Anderson and Boswell, 1964). Nitrification proceeded in a field study in Missouri as soil temperature approached 0°C, albeit at a reduced rate (Kidwaro and Kephart, 1998).

Low soil pH reduces nitrification rate. A fivefold difference in nitrification during a 15-day incubation at 23°C occurred across a range of pH from 4.5 to 6.5 in a *Typic Argiudoll* (Dancer et al., 1973). Liming an acid soil from 5.0 to 7.4 tripled nitrification during a 3–4 week incubation (Frederick, 1956). In Iowa field experiments, 89% nitrification of fall-applied anhydrous ammonia was achieved in mid-April in soils with pH > 7.5, but only 39% nitrification occurred in soils with pH < 6.0 (Kyveryga et al., 2004).

Nitrapyrin is an effective inhibitor of nitrification (Bundy and Bremner, 1973) that is commonly applied with $\mathrm{NH_4}^+$ -containing and $\mathrm{NH_4}^+$ -forming fertilizers and manure. The persistence of nitrapyrin ranges from 5 to 50 days and is dependent on soil texture, organic matter, and temperature (Keeney, 1980). The effectiveness of nitrapyrin is greater at lower temperature; therefore, it is often applied with fertilizer after soil temperatures fall below 10°C in autumn for a spring crop (Touchton et al., 1978). Dicyandiamide (DCD) is another commercially available

nitrification inhibitor and slow-release N source (Amberger, 1981) that has greater mobility in soil than nitrapyrin. Surface applications of urea and DCD can be moved into the soil with irrigation, shortly after application; but this mobility can also result in separation of DCD from NH_4^+ after urea hydrolysis (Bock et al., 1981).

A nitrification inhibitor can be effective at increasing N bioavailability and reducing NO₃⁻ leaching and denitrification. Apparent N recovery by maize grown on a sand-textured Ultisol in North Carolina was increased from 17% to 53% by including a nitrification inhibitor with urea versus urea alone (Chancy and Kamprath, 1982). After 22 cm rainfall, substantially more N remained in the upper 55 cm of soil 48 days after application with the nitrification inhibitor, than without. Similarly in a Minnesota study, applying a nitrification inhibitor with urea at 134 kg N ha⁻¹ just prior to planting increased maize grain yield 28% on a loamy coarse sand with an available water holding capacity of only 7 cm m⁻¹ (Malzer, 1989). Rainfall during the 8 weeks after application averaged 21.5 cm for the 3 years of the study, likely causing substantial NO₃⁻ leaching when urea was applied without a nitrification inhibitor.

Nitrification inhibitors affect N loss via denitrification as well as via leaching. Bioavailability of fertilizer N applied to a clay loam Ultisol increased when nitrapyrin was added with the fertilizer due to a decrease in denitrification (McElhannon and Mills, 1981). Nitrification of NH₄+-N in liquid swine manure was complete in 7 weeks without a nitrification inhibitor, but was delayed up to 15 weeks with inclusion of 50 mg nitrapyrin active ingredient per liter of manure (McCormick et al., 1983). Increased N bioavailability was attributed to reduced denitrification as little NO₃--N was found below the bands of untreated manure.

11.1.5.3 Nitrogen Leaching Reduces Nitrogen Bioavailability

Leaching of $\mathrm{NO_3}^-$ from the soil reduces bioavailability to plants and impacts environmental quality. Excess N in surface waters contributes to eutrophication (Keeney and Hatfield, 2008). High $\mathrm{NO_3}^-$ and nitrite ($\mathrm{NO_2}^-$) in drinking water and food can cause methemoglobinemia in humans and animals (National Research Council, 1972).

The amount, intensity, and timing of rainfall, evapotranspiration, soil N levels, and many other factors impact the amount of N lost by leaching. In fertilized and manured soils the timing of N uptake by crops in relation to N application and rainfall exceeding evapotranspiration are key factors (Watts and Hanks, 1978). Nitrate movement in sandy soils is thought to occur more or less through the entire soil matrix and, thus, is envisioned as moving downward with the wetting front in proportion to rainfall in excess of evapotranspiration. Nitrogen loss can be substantial and rapid. In structured soil, water moves through an incomplete volume of the soil matrix; thus, $\mathrm{NO_3}^-$ is lost from the soil proportional to its concentration and much more slowly and less completely than in sand-textured unstructured soils.

In dry climates and on heavy-textured soils, NO_3^- leaching is limited. Only 7kg NO_3^- -N ha $^{-1}$ year $^{-1}$ of 168 kg N ha $^{-1}$ applied to

a field continuously cropped to maize was found in subsurface discharge from loess soils in Iowa (Burwell et al., 1976). Thus, N applied to one crop can "carryover" and be accumulated by the next crop. For example, carryover of fertilizer N from 168 kg N ha⁻¹ N applied for maize on a silt loam soil in Wisconsin was about 50% of that applied, ranging from 32 to 106 kg N ha⁻¹ using oat to estimate bioavailability (Vanotti and Bundy, 1994). Residual N was highest when N uptake of the maize was reduced by dry weather. Thus, soil $\mathrm{NO_3}^-$ testing is often recommended for adjusting N rate recommendations in dry climates (Section 13.2).

In contrast, N leaching occurs readily in warm humid climates on sandy soils, with irrigation, and in heavier-textured soils that are tile drained. A total of 161 kg N ha⁻¹ NO₃⁻-N was leached below 120 cm soil depth in a sandy loam Hapludoll that was irrigated with 50 mm of water each time available soil water decreased to about 50 mm (50% depletion) (Timmons, 1984). Leaching of NO₃⁻-N from a split application of 185 kg N ha⁻¹ beyond 152 cm soil depth in a loamy fine sand Haplustalf was increased by irrigation, 25% above optimum, about 60 mm year⁻¹ (Gehl et al., 2005). Only about 10% of the 168 kg N ha⁻¹ applied to maize was recovered by wheat (Camberato and Frederick, 1994) or a cereal rye and annual ryegrass (*L. multiflorum* Lam.) cover crop (Shipley et al., 1992).

Nitrate-N leaching occurs in heavier-textured soil if tile drained. Nitrogen leaching ranged from 13 to 61 kg NO_3^{-} -N ha^{-1} year⁻¹ in a maize–soybean rotation on Mollisols in Iowa and from 15 to 38 kg N ha^{-1} year⁻¹ in silt loam Alfisol (Jaynes et al., 2001). Annual NO_3^{-} -N loss from a tile-drained silt loam *Typic Glossaqualf* in Indiana decreased from 38 to 15 kg N ha^{-1} by including soybean in rotation with corn, reducing N application from ≈ 300 to ≈ 200 kg N ha^{-1} , and planting a winter wheat "catch crop" after corn in the rotation (Kladivko et al., 2004). Nitrate leaching from maize grown on Coastal Plain soils in Maryland was reduced to 80% by cereal rye cover crop (Staver and Brinsfield, 1998). Field-scale watershed studies suggested that groundwater NO_3^- was reduced to 60% by the use of cereal rye cover crops.

The environmental benefit of a cover crop is dependent on when the N is mineralized and nitrified and how much is utilized by the subsequent crop. Even though forage and oilseed radish (*Raphanus sativus* L.) were as effective as rapeseed and cereal rye in recovering N from the previous crop, the captured N was released earlier in the spring in Maryland due to winter kill (Dean and Weil, 2009). Thus, high pore water NO₃ in the soil profile under the radishes suggested leaching of NO₃⁻ from the loamy sand soil was possible unless followed by an early-planted spring crop. Frost-sensitive crops, sudangrass (*S. bicolor* L.) and white mustard, also released N prematurely resulting in soil NO₃⁻ levels higher than bare fallow (Weinert et al., 2002).

Anion exchange capacity originating at low pH in weathered Alfisols, Ultisols, and Oxisols may slow NO₃⁻-N loss (Toner et al., 1989; Eick et al., 1999); however, the ability of plants (particularly crop plants) to root into these acid soil layers is questionable due to low Ca availability and/or Al toxicity (Adams and Lund, 1966; Adams and Moore, 1983).

Nitrogen fertilizer, primarily anhydrous ammonia, is often applied in relatively cold and dry climates in late fall for a crop to be planted the following spring. Although nitrification may be limited just after application due to cold soil temperatures, significant nitrification can occur in the spring as the soils warm. Substantial N loss due to leaching and/or denitrification can occur prior to crop N demand. For example, in a corn–soybean rotation, apparent N recovery of anhydrous ammonia applied for corn on a tile-drained Mollisol in southern Minnesota was only 45% for fall-applied N compared to 87% for spring-applied N (Vetsch and Randall, 2004). Nitrate-N loss to tile drainage in this environment was reduced to 14% by spring application in comparison to fall-applied N (Randall and Vetsch, 2005).

11.1.5.4 Denitrification Reduces Nitrogen Bioavailability

Denitrification, conversion of NO_3^- to N_2 or less reduced gaseous N forms (see Section 27.4 of *Handbook of Soil Sciences: Properties and Processes* for details), lowers N bioavailability and contributes to greenhouse gas emissions and global warming. Denitrification losses increase with increasing temperature, but denitrification will occur in winter months with losses to the atmosphere occurring upon thawing (Dusenbury et al., 2008). Anaerobic conditions promote denitrification as do near-neutral soil pH, increasing NO_3^- -N (McSwiney and Robertson, 2005; Millar et al., 2010) and soluble C.

Denitrification losses can be agronomically as well as environmentally important on poorly drained soils, with irrigation, application of manures or organic by-products, or reduced tillage. Denitrification losses were substantial on a clay (770 g kg⁻¹) Typic Humaquept near Québec City, Canada, on which barley was grown over a 3 year period, ranging from 12 to 45 kg N ha-1 during the snow-free season (Rochette et al., 2007). No-tillage, in comparison to moldboard plowing, resulted in a 2.5-fold increase in denitrification due to an increase in water-filled pore space. Denitrification losses in a well-drained loam soil in the same catena as the clay soil were ≤1.5 kg N ha-1. Well-drained soils in dry climates have relatively low denitrification losses. Cumulative denitrification N loss over a 2 year period from four cropping systems in the semiarid northern Great Plains ranged from 0.3 kg N ha⁻¹ for alfalfa (Medicago sativa L.)-perennial grass to 1.3 kg N ha⁻¹ for continuous wheat (Dusenbury et al., 2008).

High rates of N_2O flux from the soil, 0.24–1.06 kg N ha⁻¹ day⁻¹, occurred from three vegetable production systems in Santa Barbara County, California (Ryden and Lund, 1980). Peak N_2O emissions followed the first furrow irrigation after N fertilization. Annual emissions were estimated to range from 20 to 42 kg N ha⁻¹. Organic materials high in bioavailable C that stimulate microbial respiration may create an anaerobic microenvironment, creating conditions suitable for denitrification (Rice et al., 1988).

Greater denitrification occurred with alkaline-hydrolyzing fertilizers, anhydrous ammonia, and urea, in comparison to acidic fertilizers, because of increased soil pH and water soluble organic carbon with the alkaline fertilizers (Mulvaney et al., 1997).

Denitrification losses of N from banded urea fertilizer (applied at 218 kg N ha⁻¹) for maize grown on a furrow irrigated, well-drained Aridic Argiustoll in Colorado were 3.2 and 1.7 kg N ha⁻¹ in each year of the study (Bronson et al., 1992). Peak N₂O emissions were coincident with irrigation and rainfall and were reduced by slowing the conversion of urea to NO_3^- by including the nitrification inhibitor, nitrapyrin, with the banded fertilizer. Cumulative denitrification N losses from maize grown with 210 kg N ha⁻¹ as surface-applied urea, no-tillage, and sprinkler irrigation on two Mollisols in Argentina were 9.8 and 2.1 kg N ha⁻¹, for preplant and sidedress N application, respectively (Sainz Rozas et al., 2001). Most of the N loss occurred when water-filled pore space exceeded 80%.

11.1.5.5 Ammonia Volatilization Reduces Nitrogen Bioavailability

Volatilization of NH₃ from fertilizer and manure can be substantial, easily >25% of the N content of several fertilizer and manure sources (Lauer et al., 1976; Fillery et al., 1984). Direct loss of anhydrous ammonia and aqua ammonia fertilizers can occur through improper soil application (Parr and Papendick, 1966) or application in irrigation water (Gardner and Roth, 1984). Ammonia losses can also occur from fertilizers that do not initially contain NH₃ if they are left on or near the soil surface and conditions are suitable for conversion of NH₄⁺ to NH₃. pH and temperature are the two primary factors affecting NH₃ loss. Increasing pH increases NH₃ volatilization because it increases the proportion of ammoniacal-N in the NH₃ form (du Plessis and Kroontje, 1964).

$$NH_4^+ + OH^- \leftrightharpoons NH_3 + H_2O$$
 (11.1)

Increasing temperature increases the driving force for NH_3 volatilization by decreasing the pK_a for the equilibrium (Koelliker and Kissel, 1988). Wind also increases NH_3 loss (Fillery et al., 1984), as long as it does not impede urea hydrolysis by drying the reaction site.

11.1.5.5.1 Ammonia Volatilization from Fertilizers

Ammonium sulfate or $(NH_4)_2HPO_4$ application to calcareous soils can result in substantial NH_3 loss (Fenn and Kissel, 1973). However, when applied to lower pH soils most NH_4^+ -containing fertilizers result in little NH_3 volatilization (Volk, 1959). In contrast, NH_3 volatilization is likely with urea-containing fertilizers in many situations because urea hydrolysis increases pH (Overrein and Moe, 1967) as NH_4^+ is formed.

$$CO(NH_2)_2 + H^+ + 2H_2O \rightarrow 2NH_4^+ + HCO_3^-$$
 (11.2)

Low buffer capacity soils result in greater $\mathrm{NH_3}$ volatilization due to greater increases in pH and lower retention of exchangeable $\mathrm{NH_4^+}$ (Ferguson et al., 1984).

Ammonia volatilization losses from urea are higher when applied to crop residues (e.g., no-tillage cropping systems),

pasture, or turfgrass in comparison to the soil surface, partly because residues and plant tissues have high urease activity (Torello and Wehner, 1983; Dick, 1984), resulting in rapid urea hydrolysis and substantial pH changes on low buffered materials (McInnes et al., 1986). Increased temperature promoted urea hydrolysis (Broadbent et al., 1958; Fisher and Parks, 1958) as well and also increased the proportion of ammoniacal-N in the NH₃ form (Koelliker and Kissel, 1988). Moisture is required for urea hydrolysis to occur (Ernst and Massey, 1960), but losses are enhanced as drying concentrates the NH₄+ (Hargrove et al., 1977; McInnes et al., 1986). Rainfall of 28 and 33 mm incorporated urea into the soil and halted NH₃ volatilization, whereas irrigation of 2.5 mm increased loss (McInnes et al., 1986). Irrigation or rainfall amount must be sufficient to incorporate the N into the soil so as not to enhance losses (Kissel et al., 2004).

Fertilizer application method and form can affect NH₃ volatilization. Surface application of urea-containing fertilizers greatly enhanced NH₃ volatilization as determined by crop response (Mengel et al., 1982; Touchton and Hargrove, 1982; Fox and Piekielek, 1987). Hargrove (1988) suggested that a depth of 5–10 cm would prevent NH₃ loss from urea on most soils. Banding urea versus a broadcast application generally reduces NH₃ losses as well. Including a urease inhibitor (Schlegel et al., 1986), coating (Matocha, 1976), or encapsulating urea (Knight et al., 2007) also reduce NH₃ volatilization.

11.1.5.5.2 Ammonia Volatilization from Manures

Nitrogen applied to surface-applied manures is subject to NH₃ volatilization losses because potentially volatile N compounds are a significant percentage of the total N content. Urea comprised nearly 70% of the N in urine from ruminants (Bristow et al., 1992). Approximately 30%-50% of the total N content of various poultry manures was uric acid- and urea-N (Nicholson et al., 1996; Fujiwara and Murakami, 2007). Manure pH, which fosters NH₃ and enhances volatilization, may exceed 8.0 (Nicholson et al., 1996), greatly reducing N availability from poultry manures. Nearly 100% of the initial NH₄+-N content of a poultry litter was lost by NH₃ volatilization in ≈8 days after application in summer when conditions were hot, dry, and windy (Sharpe et al., 2004). However, NH₃ loss in winter was only 10% of the NH4+-N content. Rainfall shortly after manure application to the soil surface reduces NH₃ volatilization by transporting volatile N forms into the soil (Cabrera and Vervoort, 1998; Sharpe et al., 2004). Ammonia loss from surface-applied cattle slurry, which was not incorporated, exceeded 40% of the initial NH₄+-N content, but immediate incorporation with disk harrow, chisel plow, or moldboard plow substantially reduced loss to 5%, 9%, and 1%, respectively (Thompson and Meisinger, 2002). Peak NH₃ loss occurs soon after application (Marshall et al., 1998), so rainfall must also occur soon after application to be effective in reducing NH₃ volatilization.

11.1.5.5.3 Ammonia Volatilization from Plant Tissues

Ammonia volatilization directly from plant tissues can be substantial. Harper et al. (1987) estimated that 21% of the 73 kg ha⁻¹

fertilizer N applied in the spring of the year in Georgia was volatilized from wheat tissue. Direct volatilization of NH $_3$ from maize tissues in Nebraska was equivalent to 10%–20% of the fertilizer N applied, and apparent total N losses from aboveground plant tissues ranged from 45 to 81 kg N ha $^{-1}$ (Francis et al., 1993). This loss was equivalent to 50%–75% of the unaccounted-for N in 15 N balance calculations. Although the results of these studies suggest NH $_3$ volatilization from plant tissue is substantial, rarely is this loss mechanism considered or quantified in N studies.

11.1.6 Ammonium in the Interlayer of 2:1 Clay Minerals

Ammonium ions occur in the interlayer of 2:1 clay minerals, particularly vermiculite and degraded illite (Nommik and Vahtras, 1982). Often, this phenomenon is referred to as "fixation," implying zero bioavailability. In reality, however, interlayer $\mathrm{NH_4^+}$ exchanges with the soil solution to some degree and is, therefore, available for plant uptake. Fixation of nearly $10\,\mathrm{mg}\,\mathrm{kg}\,\mathrm{NH_4^+}$ -N (10% of that added as ($\mathrm{NH_4}$)₂SO₄) occurred in less than 1 day in two vermiculitic soils (Broadbent, 1965). Green et al. (1994) found up to 23% of the N applied in urea was fixed as $\mathrm{NH_4^+}$ after 20 days of anaerobic incubation. However, nearly half the fixed $\mathrm{NH_4^+}$ was released during nitrification after 15 days of aerobic incubation (Green et al., 1994). Plant (Li et al., 1990) and microbial (Kelley and Stevenson, 1987) utilization of solution $\mathrm{NH_4^+}$ also resulted in the release of fixed $\mathrm{NH_4^+}$.

11.1.7 Predicting Nitrogen Bioavailability

Blackmer (1999) outlined many indices of N bioavailability; including Mitscherlich "b" and "c" values, Fried and Dean "A" values, Dean "a" values, and several biological and chemical tests for estimating N mineralization. Sims (Chapter 13) overviewed several inorganic N bioavailability tests including the residual inorganic N, preplant soil profile nitrate (PPNT), and the presidedress soil nitrate (PSNT) tests. The recently developed Illinois soil nitrogen test (ISNT), a purported indicator of mineralizable N, was also discussed by Sims. Girma and Raun (Chapter 15) discussed the use of optical sensors to make in-season estimates of N bioavailability by assessing crop canopy size and greenness. Tissue testing and hand-held chlorophyll meters were the precursors to optical sensors (Schepers et al., 1992) and achieved much the same goal. Adapt-N is a promising web-based tool used to make N recommendations for maize in New York that dynamically simulates the impact of weather on N transformations and transport to estimate crop N accumulation and predict N need (Melkonian et al., 2008). Given the complexity of the N cycle, the importance of temperature and moisture in affecting N bioavailability, and the economic and environmental costs of errors in N management, it is no wonder a sophisticated tool such as Adapt-N is needed to predict N bioavailability and improve N management.

11.2 Phosphorus Availability

Andrew Sharpley

11.2.1 Introduction

Phosphorus (P) is an essential nutrient for plant growth. The low concentration ($100-3000\,\mathrm{mg}\,P\,kg^{-1}$) and solubility ($0.01-0.10\,\mathrm{mg}\,P\,L^{-1}$) of P in soils, however, make it a critical nutrient limiting plant growth. In natural ecosystems, P availability in soil is controlled by the sorption, desorption, and precipitation of P released during weathering and dissolution of rocks and minerals of low solubility. Thus, soil P availability is generally inadequate for crop needs in production agriculture. To meet these needs, P is added as fertilizers or animal manures to buildup or maintain soil P availability at predetermined optimum levels. In this section, P availability is defined as that P in soil or water that is available by desorption and dissolution processes for uptake by plants in terrestrial and aquatic ecosystems.

The components, forms, availability, and cycling of P in soil are conceptualized in Figure 11.1. Complex and interrelated processes determine the amounts and availability of several inorganic and organic forms of P in soil. This section will describe these processes occurring in the soil, how they are affected by agricultural management, how we attempt to optimize soil P availability for crop production, and how this can affect water quality.

11.2.2 Forms and Amounts in Soil

Soil P exists in inorganic (P_i) and organic (P_o) forms (Figure 11.1). Inorganic P forms are dominated by hydrous sesquioxides,

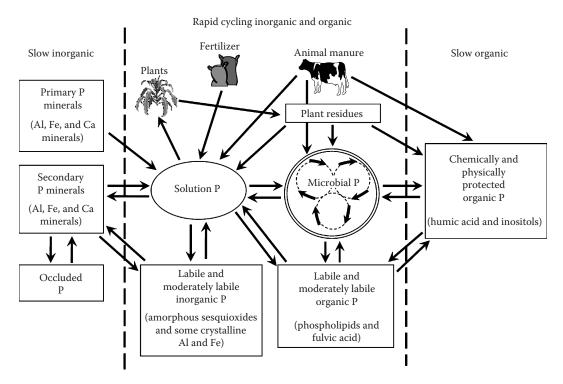

FIGURE 11.1 The soil P cycle: its components, forms, and flows. (Adapted from Stewart, J.W.B., and A.N. Sharpley. 1987. amorphous, and crystalline Al and Fe compounds in acidic, noncalcareous soils, and by Ca compounds in alkaline, calcareous soils (Figure 11.1 and Table 11.1). Organic P forms include relatively labile phospholipids and fulvic acids; more resistant forms comprise inositols and humic acids (Figure 11.1). Forms generalized in Figure 11.1 are not discrete entities, as intergrades and dynamic transformations between forms occur continuously to maintain equilibrium conditions. These

Source: Adapted from Sharpley, A.N., H. Tiessen, and C.V. Cole. 1987. Soil phosphorus forms extracted by soil tests as a function of pedogenesis. Soil Sci. Soc. Am. J. 51:362–365.

approximated forms of P are assigned based on the extent to which sequential extractants of increasing acidity or alkalinity can dissolve soil P (Hedley et al., 1982; Tiessen and Moir, 2007; Zhang and Kovar, 2008).

In most soils, the P content of surface horizons is greater than subsoil, due to the sorption of added P and greater biological activity and accumulation of organic material in surface layers. However, soil P content varies with parent material, extent of pedogenesis, soil texture, and management factors, such as rate and type of P applied and soil cultivation. These factors also influence the relative amounts of P_i and P_o . In most soils, 50%–75% is P_i , although this fraction can vary from 10% to 90% (Table 11.1). Generally, Ca- P_i decreases with weathering, whereas amorphous Al and Fe- P_i and P_o forms tend to increase, due in part to changes in soil clay fraction from basic primary minerals to Al- and Fe-dominated oxides (Table 11.1).

Phosphorus additions are usually needed to maintain adequate available soil P for plant uptake. The level of these additions varies with both soil and plant type (Pierzynski and Logan, 1993). Once applied, P is either taken up by the crop, becomes weakly (physical) or strongly (chemical) adsorbed onto Al, Fe, and Ca surfaces, or incorporated into organic P (McLaughlin et al., 1988; Ottabong et al., 1997; Zhang and MacKenzie, 1997) (Figure 11.2). As P_i generally supplies most of the P taken up by crops in productive agricultural soils, more attention has been focused on the availability of P_i rather than P_o, following P additions.

Overall, soil pH is the main property controlling the nature of P_i forms, although Al, Fe, Mn, and Ca content determine the

^a Bioavailable P_i is resin P_i and residual P is chemically resistant, mineral, and occluded P_i and P_o as designated on Figure 11.1.

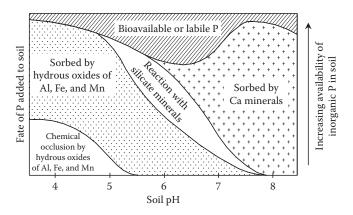

FIGURE 11.2 Approximate representation of the fate of P added to soil by sorption and occlusion in inorganic forms, as a function of soil pH. (Adapted from Buckman, H.O., and N.C. Brady. 1970. The nature and properties of soils. The Macmillan Publishing Co., Collier-Macmillan Limited, London, U.K.)

amounts of these forms (Figure 11.2). In acid soils, amorphous and hydrous oxides of Al, Fe, and Mn dominate P sorption processes, while Ca compounds dominate P sorption and precipitation reactions in alkaline soils. As a result, P availability is greatest at soil pH between 6 and 7 (Figure 11.2). Immobilization of P_i by these processes renders a portion of the added P unavailable for

plant uptake (Figure 11.3). Mehlich-3 soil P decreased with time after application of P to a Kingsbury clay (*Aeric Ochraqualfs*; pH of 5.7) and Hagerstown silt loam (*Typic Hapludalfs*; pH of 6.8) incubated at room temperature (25°C) and field moisture (about 30% water). At the same time, P_i becomes more tightly bound with Al and Fe complexes (Figure 11.3). This simple soil-P incubation illustrates why the removal of P_i from soil by crops is generally low. For the United States, an average 29% of P added in fertilizer and manures is removed by harvested crops, ranging from <1% in Hawaii to 71% in Wyoming (National Research Council, 1993). The low recovery reflects the predominance of high P fixing soils in Hawaii.

Even though P_i has generally been considered the major source of plant-available P in soils, the mineralization of labile P_o has also been shown to be important in both low-fertility and high-fertility soils (Stewart and Tiessen, 1987; Oehl et al., 2001; Chen et al., 2002; Condron et al., 2005). Amounts of P_o mineralized in temperate dryland soils range from 5 to $20 \, \text{kg P ha}^{-1} \, \text{year}^{-1}$ (Stewart and Sharpley, 1987). Mineralization of soil P_o tends to be higher in the tropics (67 to 157 kg P ha⁻¹ year⁻¹), where distinct wet and dry seasons and higher soil temperatures enhance microbial activity. In contrast, P_o compounds may also become resistant to hydrolysis by phosphatase through complexation with Al and Fe (Tate, 1984).

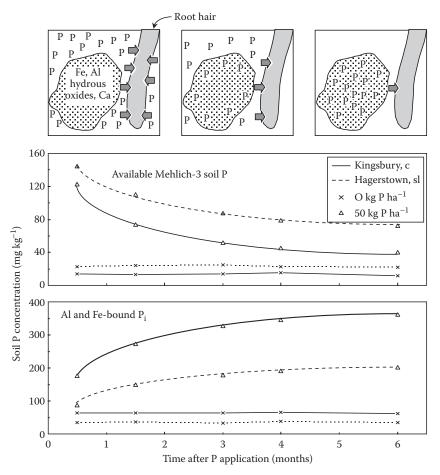

FIGURE 11.3 The change available (Mehlich-3 P) and adsorbed soil P (Al- and Fe-bound) with time after application of P.

11.2.3 Principles of Analysis

The various forms and amounts of P_i and P_o in soil can be estimated by extraction with acids and alkalies that dissolve specific complexes binding P. The most common methods and their background are given by Olsen and Sommers (1982), Turner et al. (2005), Tiessen and Moir (2007), Kovar and Pierzynski (2008). A wide range in methods and principles exists for effective recovery of P based on soil type, environment, and level of detail required. This is particularly true for available soil P_i estimation, which has traditionally been based on acid dissolution (acetic, citric, hydrochloric, lactic, nitric, and sulfuric), anion exchange (acetate, bicarbonate, citrate, lactate, and sulfate), cation complexation (citrate, fluoride, and lactate), or cation hydrolysis (buffered bicarbonate). Several excellent reviews of these methods are available for further reading (Kamprath and Watson, 1980; Fixen and Grove, 1990). In the United States, the most common soil P tests have been Mehlich-1 (Mehlich, 1953), Bray-1 (Bray and Kurtz, 1945), and Olsen P (Olsen et al., 1954); however, most laboratories have converted to the multielement Mehlich-3 (Mehlich, 1984) or AB-DTPA (Soltanpour and Schwab, 1977) extractants, in the past decade (Carter and Gregorich, 2007; Sims, 2008).

It is unlikely that an extractant would exclusively measure a single pool of soil P_i, although some components of extractants are aimed at specific pools. For example, F in the Bray-1 extractant exchanges with Al-bound P_i, with the assumption that this Al-bound P_i contributes to available P in acid soils, while the inclusion of EDTA in Mehlich-3 means this extractant estimates P associated with Fe and Al amorphous complexes. The success of any extractant to estimate available P depends on the appropriateness of the chemical used relative to dominant soil properties controlling P reactivity. Alternative methods utilize P-sinks, such as anion-exchange resins (AER), ion-exchange membranes, and Fe-oxide impregnated paper, to determine the quantity of soil P available to plants with negligible chemical extraction (Sharpley et al., 1994). These methods more closely mimic rhizosphere conditions and often provide comparable or better correlations with crop response than chemical extractants (Table 11.2).

11.2.3.1 Anion-Exchange Resins

AER are the most common P-sink method for assessing available soil P_i. The procedure typically involves the use of chloride saturated resin at a 1:1 resin-to-soil ratio in 10–100 mL of water or weak electrolyte for 16–24h (Amer et al., 1955; Olsen and Sommers, 1982). To prevent the diffusion of P from the soil to the resin from being the rate-limiting step, resins should be intimately mixed with the soil, which creates difficulties in separating resin from soil for P analysis. Soil can be ground to a smaller size than the resin, but this probably changes soil P release characteristics. Resin and soil may also be separated by enclosing the resin in a mesh bag, which may limit resin–soil contact or float resin from soil in a sucrose solution (Thien and Myers, 1991). Skogley et al. (1990) encapsulated a mixture of anion- and cation-exchange resins in a mesh sphere. Greenhouse studies

indicated that the correlation between P uptake by sorghumsudangrass and resin-sphere results were as good or better than those with the Olsen P soil test (Table 11.2).

11.2.3.2 Ion-Exchange Membranes

A similar approach using ion-exchange resin impregnated membranes has been investigated by several researchers (Abrams and Jarrell, 1992; Qian et al., 1992; Saggar et al., 1992). Impregnation of the resin onto a plastic membrane facilitates separation of the resin beads from the soil and may eliminate the soil grinding step. Also, an extraction time as short as 15 min can be used, without reducing the accuracy of predicted P availability for a wide range of soils (Qian et al., 1992). In pot studies, the resin membranes have provided a better index of P availability than conventional chemical extraction methods for canola and ryegrass (Table 11.2).

11.2.3.3 Iron-Oxide Impregnated Paper

Another P sink that has received attention is Fe-oxide impregnated filter paper (Fe–O strip), which has successfully estimated available P_i in a wide range of soils and management systems (Menon et al., 1989b, 1990; Sharpley, 1991; Chardon, 2008) (Table 11.2).

Wide-spread adoption of P-sink methods for routine soil testing has not yet occurred in the United States, although parts of Brazil have used the method for the last decade (van Raij et al., 1986). As the P-sink methods operate with limited chemical extraction, they are more suited to a wide range of soils, irrespective of management history (Yang et al., 1991; Qian et al., 1992; Somasiri and Edwards, 1992; Myers et al., 2005). Where fertilizer history is unknown and frequent changes in fertilizer type, including rock phosphate, may have been made, it is difficult to choose the appropriate soil test. For example, Olsen P can underestimate and Bray-1 P overestimate P availability in soils amended with rock P, while P-sink methods have provided accurate estimates when KCl rather than CaCl₂ is used as the support medium (van Raij et al., 1986; Menon et al., 1989a; Saggar et al., 1992). Even so, detailed field calibration and improvement in standardized methodology will be essential before any of the P-sink approaches can be used routinely to estimate available soil P and make reliable fertilizer recommendations.

Phosphorus isotopes P³² and P³³ have also been widely used to characterize soil P availability. Using laboratory incubation, greenhouse pot, and limited field plot studies, valuable insights have been gained into soil P availability in terms of exchange kinetics, plant-available forms, and the rate, extent, and direction of P cycling in soils. Readers are directed to excellent reviews by Fardeau et al. (1996), Di et al. (1997), and Frossard and Sinaj (1997) for more information.

11.2.4 Cycling in Soil

Dynamic processes involved in P cycling are chemical and biological (Figure 11.1). Chemical processes include precipitation—dissolution—and sorption—desorption. Biological processes involve immobilization—mineralization initiated by P uptake

and decay of plants. Also, soil faunal and floral activities often modify the direction, extent, and rate at which these chemical and biological processes occur.

11.2.4.1 Chemical Processes

Precipitation-dissolution processes differ from sorptiondesorption in that the solubility product of the least soluble P compound in the solid phase controls dissolution and, thus solution P concentration, whereas solution P controls the amount of P sorbed (Syers and Curtin, 1989). In reality, retention of P by soil material is a continuum between precipitation and surface reactions.

11.2.4.1.1 Precipitation-Dissolution

In general, Ca controls these reactions in neutral or calcareous environments, while Al and Fe are the dominant controlling cations in acidic environments. Apatite is the most common primary P mineral (Ca_{10} (PO₄)₆ X₂, where X is F or OH). Apatite dissolution requires a source of H+ from soil or biological activity and a sink for Ca and P (Mackay et al., 1986; Smillie et al., 1987):

$$Ca_{10}(PO_4)_2X_2 + 12H^+ = 10Ca^{2+} + 6H_2PO_4^- + 2X^-$$
 (11.3)

and occurs during soil development due to weathering (Walker and Syers, 1976). Even though the rate of apatite weathering or dissolution will vary with rainfall and temperature, it is still difficult to predict this first step in the P cycle (Pierzynski, 1991; Pierzynski et al., 2005).

Precipitates in Ca systems occur in the following sequence; monocalcium phosphate [Ca (H2PO4)2], dicalcium phosphate dihydrate (Ca HPO₄ 2H₂O), octacalcium phosphate

^a Relationship between relative crop yield and soil P test.

[Ca₈H₂(PO₄)₆·5H₂O], and finally hydroxyapatite [Ca₁₀(PO₄)₆ (OH)₂] or fluorapatite [Ca₁₀(PO₄)₆F₂], which have low solubilities and should, thus, control soil solution P concentration (Lindsay et al., 1989; Syers and Curtin, 1989).

In Al- and Fe-dominated soils, few well-crystallized precipitates have been observed. Generally, P reacts with Al oxides to form amorphous Al P or organized phases such as sterretite $[Al(OH_2)_3 \ HPO_4 \ H_2PO_4]$ and with Fe oxides to such precipitates as tinticite $[Fe_6 \ (PO_4)_4 \ (OH)_6 \cdot 7H_2O)$ or griphite $[Fe_3 \ Mn_2 \ (PO_4)_2 \cdot 5(OH)_2]$ (Hsu, 1982; Lindsay et al., 1989). Many other amorphous mixed Al–Fe–Si–P compounds have been observed in soils with high P concentrations from phosphatic parent material or large fertilizer or manure applications (Lindsay et al., 1989; Pierzynski et al., 1990b).

11.2.4.1.2 Sorption/Desorption

In most soils, sorption-desorption processes describe P uptake and release by soils that control P availability better than precipitation-dissolution reactions. In this section, the term "sorption" covers surface "adsorption" and subsequent penetration of P into the retaining component or "absorption." Sorption curves or isotherms have been used extensively to describe the relationship between the amount of P sorbed and that remaining in solution (Figure 11.4). For a given solution P concentration, there is a large difference in the amount of P sorbed by the three soil types given as examples. In general, clay content approximates the reactive surface area of a soil responsible for P sorption (Syers et al., 1971; Juo and Fox, 1977; Sharpley et al., 1984a; Hedley et al., 1995). This surface reactivity is a function of the amount and type of hydrous oxides of Al and Fe and reactive Ca components present, other ions (Ca- or Na-dominated), pH of the system, and reaction kinetics.

Even in calcareous soils, hydrous ferric oxides can influence P sorption reactions (Holford and Mattingly, 1975a, 1975b). The types of bonding associated with hydrous oxides and pH

dependency have been described in detail by Sample et al. (1980), Uehara and Gillman (1981), and White (1980) (Figure 11.5). Ligand exchange of P at hydrous OH and Fe oxide surfaces results in the formation of monodentate, bidentate, or binuclear complexes (Figure 11.5). As soil solution pH increases, P sorption is decreased by the greater negative charge at the oxide surface and reduced polarization of the Al or Fe–O bond (Figure 11.5).

Soil P sorption has been characterized by parameters calculated from the Langmuir equation:

$$S = \frac{(k S_{\text{max}} C)}{1 + kC} \tag{11.4}$$

where

S is sorbed P

C is solution P concentration

 S_{max} is the maximum amount of P that can be sorbed k is an "affinity" constant describing binding energy

Phosphorus sorption maximum is calculated as the reciprocal of the slope of the plot C/S and C and binding energy as the slope/ intercept of the same plot (Olsen and Watanabe, 1957; Syers et al., 1973; Graetz and Nair, 2008) (Table 11.3). Equilibrium P concentration is the solution P concentration at which no net sorption or desorption occurs (Figure 11.4 and Table 11.3). These parameters have been widely used to quantify the extent of specific soil reactions and effects of soil types, counter ion and background electrolyte, P source, and soil management on P sorption (Goldberg and Sposito, 1985; Fixen and Grove, 1990). However, the theoretical assumptions of the Langmuir equation were questioned (White, 1980; Barrow, 1989), as sorbed P carries charges that decrease the surface charge and potential of the sorbing surface, leading to large errors in the estimates of S_{max} (Kuo, 1988). The Freundlich equation often fits data better than the Langmuir equation but does not estimate S_{max} (Barrow, 1978).

Organic anions can compete with P for similar sorption sites on soil surfaces (Yuan, 1980; Hue, 1991; Ohno and Crannell, 1996). However, P sorption can be increased when the addition of organic compounds to amorphous oxides in soil impedes their crystallization and increases specific surfaces (Table 11.3). Also, humic compounds can complex with Fe, Al, and to a lesser extent Ca and sorb P (Levesque and Schnitzer, 1967; Inskeep and Silvertooth, 1988; Frossard et al., 1995).

The release of sorbed P into solution or desorption is not completely reversible. Thus, desorption curves are displaced to the left of the sorption curves. This hysteresis effect is the result of precipitation (Veith and Sposito, 1977), occlusion (Uehara and Gillman, 1981), solid-state diffusion (Barrow, 1983), and bidentate or binuclear bonding with the colloid surface (Hingston et al., 1974).

Several studies have reported that desorption of soil P during a short period of time is a low-activation energy process (Sharpley et al., 1981). The work of Kuo and Lotse (1974) and Evans and Jurinak (1976) reported that the activation energy for

P desorption was between 2 and 3 kcal mol⁻¹. The low-activation energies led these researchers to suggest that the desorption of soil P during short reaction times may be limited more by the diffusion of the desorbed P through the stagnant water films present around the soil particles and within the soil aggregates than by the chemical reaction. Although higher-activation energies (20 kcal mol⁻¹) were reported by Barrow and Shaw (1975), they were determined for a longer reaction period (up to 100 days) and represent the transfer of P between desorbable and fixed forms. It has been suggested that there is a continuous range of activation energies for soil P desorption (Posner and Bowden, 1980). During the initial stages of desorption, P held at low-activation energies is desorbed; during the later stages, P held at higher-activation energies is desorbed.

More detailed analysis and review of these chemical processes controlling soil P availability are given by Barrow (1985), Lindsay et al. (1989), Syers and Curtin (1989), Fixen and Grove (1990), Frossard et al. (1995), Condron et al. (2005), and Pierzynski et al. (2005).

11.2.4.2 Biological Processes

Uptake of soluble P by bacteria and fungi, stimulated by the addition of microbial substrates such as litter and crop residues, and release of P as the result of cell lysis or predation (Coleman et al., 1983; Tiessen et al., 1984; Frossard et al., 2000; Jakobsen et al., 2005) are represented in Figure 11.1 as a revolving wheel. This is done deliberately to emphasize the central role of the microbial population in P cycling and availability. For example, if the wheel is stopped or slowed down by lack of C inputs, the supply of P to plants will be limited to the quantity of labile P_i. If the wheel is operating, then solution P is constantly being replenished from labile P_i and P_o forms. Generally, microbial biomass P ranges from 5 to 100 mg kg⁻¹ (Srivastava and Singh, 1991; Joergensen et al., 1995; Oberson et al., 1997). As a result, large amounts of P can turnover through microbial biomass annually (He et al., 1997; Oehl et al., 2001; Jakobsen et al., 2005). For example, in a study of P cycling through soil microbial biomass in England, Brookes et al. (1984) measured annual P fluxes of 5 and 23 kg P ha⁻¹ year⁻¹ in soils under continuous wheat and permanent grass, respectively. Although biomass P flux under continuous wheat was less than P uptake by the crop (20 kg P ha-1 year-1), annual P flux in the grassland soils was greater than P uptake by the grass (12 kg P ha⁻¹ year⁻¹).

Within the microbial cell, P exists as a wide variety of compounds, principally RNA (30%–50%), acid soluble P_i and P_o (15%–20%), phospholipids (<10%), and DNA (5%–10%) (Stewart and McKercher, 1982; Condron et al., 2005). If the microbial cell is ruptured or lysed, all these compounds will be released to the soil solution to react with both inorganic and organic soil components to form a host of P_i and P_o compounds of differing solubility or susceptibility to mineralization. The rate of mineralization of P_o forms depends largely on phosphatase activity, which, in turn, can be controlled by solution P concentration (McGill and Cole, 1981; Chen et al., 2002). Stable P_o accumulates in both chemically resistant and aggregate protected forms (Marshall, 1971; Tisdale and Oades, 1982; Condron et al., 2005).

Chemically or physically protected P_o may be slowly mineralized as a by-product of the mineralization of overall soil organic matter or by specific enzyme action in response to the need for P_o . Therefore, organic matter turnover, as well as solution P_o concentration and the demand for P_o by microbial and plant components, will be factors controlling the lability of P_o (Richardson, 2000; Turner et al., 2002; Condron et al., 2005). A continuous drain on soil P_o pools by cultivation and crop removal will rapidly deplete labile P_o forms and, thereby, reduce available soil P_o (Hedley et al., 1982; Sharpley and Smith, 1985; Tiessen et al., 1992).

11.2.4.3 Fauna and Flora Processes

The effects of soil fauna (e.g., earthworms and termites) and flora (actinomycetes, bacteria, and fungi) on soil physical, chemical, and biological processes have been extensively studied and reviewed (Reichle, 1977; Lee, 1985; Edwards, 2004). This section outlines

the role of the more important of these, earthworms and mycorrhizae, in soil P cycling and their impact on soil P availability.

11.2.4.3.1 Earthworms

Under favorable soil temperature and moisture conditions, earthworms have been found annually to consume 100% of the litter of an evergreen oak forest in Japan (8 Mg ha⁻¹ year⁻¹ by A. pheretima; Sugi and Tanaka, 1978) and mixed deciduous forest in England (3 Mg ha⁻¹ year⁻¹ by Lumbricus terrestris; Satchell, 1967); about 30% of the litter decomposed each year in grass savanna (Lavelle, 1978) and 100% of added cattle manure (17-30 Mg ha⁻¹ year⁻¹, Guild, 1955). During this consumption, earthworms commonly ingest 100-500 Mg soil ha-1 year-1 (equivalent to 0.5-3.0 cm of top soil) (Russell, 1973). Consequently, earthworms can have a major influence on soil physical, chemical, and biological properties through incorporation and assimilation of plant litter and associated ingestion of soil material (Lee, 1985; Lavelle, 1988). Egestion as surface and subsurface cast material can rapidly redistribute P in a soil profile, increasing the availability and potential for uptake. Also, earthworm burrowing can allow a greater soil volume to be exploited by plant roots and decrease susceptibility of plants to water stress. Earthworm burrows open to the soil surface increase infiltration rates, enhancing nutrient movement into the profile via macropore flow (Sharpley et al., 1979; Germann et al., 1984; Edwards et al., 1989; Shuster et al., 2003; Dominguez et al., 2004).

The main source of P affected by earthworms is soil organic matter, which includes plant litter in various stages of decomposition, roots, and organic matter in the soil with its complement of microflora and fauna. Ingestion, maceration, and intimate mixing of organic matter with soil increase the rate of humification and mineralization. Although most organic matter undergoes little chemical change during passage through the earthworms' gut, it is finely ground with the increased surface area exposed to microbial activity, facilitating further decomposition. The 5- to 10-fold increase in P content and availability in earthworm casts results from enhanced mineralization of organic P, enrichment of clay-sized particles in casts, and a reduction in P sorption capacity of soil by organic matter blockage (Sharpley and Syers, 1977; Sharpley et al., 1992). Thus, most of the additional P present in casts is held in more physically sorbed than chemisorbed forms, which are readily available to plants.

Both microbial population and activity are increased during passage through the earthworms' gut as a function of the organic matter content of the initial food source (Tiwari, 1979; Gorbenko et al., 1986; Scheu, 1987). Parle (1963) observed that the numbers of bacteria and actinomycetes increased 1000-fold during passage through the gut, and oxygen consumption remained higher in earthworm casts than in soil for 50 days, indicating an increased microbial activity. This enhanced activity is probably responsible for the increased phosphatase activity found in earthworm casts compared to underlying soil (Sharpley and Syers, 1977).

As a result of the incorporation and decomposition of plant material in soil via earthworm activity, soil fertility and productivity can be improved (Lavelle et al., 1989; Edwards et al., 1995; Katsvairo et al., 2002). For instance, Katsvairo et al. (2002) found that earthworm activity contributed to a 15%–40% increase in corn yields in a soybean (*Glycine max* [L.] Merr.)—wheat (*Triticum aestivum* L.)/clover (*Trifolium pretense* L.)—corn (*Zea mays* L.) rotation on a Kendaia—Lima silt loam in Aurora, New York.

Differences in tillage operation and frequency; amount, type, and quantity of residues left on the soil surface; soil type and climate; and application of manures can influence earthworm populations, species composition, and activity (Pankhurst et al., 1995; Edwards and Bohlen, 1996). For example, several studies have reported an increase in the population and activity of earthworms under reduced compared to conventional tillage practices, concomitant with an increase in food or energy supply (Edwards et al., 1989; Trojan and Linden, 1998; Shipitalo et al., 2000).

The application of manure has been shown to encourage the buildup of earthworm populations in cropped soils to a greater extent than in grass, where there tends to be more decaying organic matter (i.e., food) than in cropped soils (Edwards, 1980; Satchell, 1983). For instance, application of dairy manure (50–400 kg P ha⁻¹) to a rape (*Brassica napus* L.)—sugar beet (*Beta vulgaris* L.)—grass rotation increased the numbers of surface feeding *L. terrestris* by directly increasing their food supply and associated microorganisms (Andersen, 1983). Similarly, the application of dairy manure (20 Mg manure ha⁻¹ year⁻¹ for 14 year) increased earthworm population, diversity, and activity (mainly *Aporrectodea* and *Lumbricus* genus) in a Le Bras clay loam in Quebec (Estevez et al., 1996).

The potential for earthworm activity to incorporate surface applied manures was demonstrated by Chardon et al. (2007). Disappearance of manure patches deposited by grazing cattle, was partially attributed to earthworm activity, with only 15% of dry matter and 22% of total P in manure patches remaining 234 days after deposition on a permanently grassed sandy soil from Heino, the Netherlands (Chardon et al., 2007). While the manure can remain a long-term source of P to soil leachate, the overall risk of P runoff was reduced as the grassland soil could retain most of the P leached from patches.

11.2.4.3.2 Mycorrhizal Associations

Mycorrhizae are widespread under natural conditions, with vesicular-arbuscular mycorrhizae (VAM) most common in agricultural soils (Smith and Read, 1997; Jakobsen et al., 2005). In fact, VAM are formed by approximately two-thirds of all plants species (Fitter and Moyersoen, 1996) and fungi belonging to the recently established phylum Glomeromycota (Schüssler et al., 2001). Three primary mechanisms by which VAM enhances soil P availability are increased physical exploration of the soil, chemical modification of the rhizosphere, and physiological differences between VAM and plant roots (Read, 2002). For example, extensive hyphal growth of VAM reduced the distance for diffusion of P in soil, thereby increasing uptake. This effect is greater when diffusion limits uptake (Gerdemann, 1968; Facelli and Facelli, 2002). Consequently, a greater response to VAM

infection has been exhibited in coarse than in fine rooted plant species (Crush, 1973), in high than in low P sorbing soils (Yost and Fox, 1979), and in soils than in solution culture (Howeler et al., 1982). In addition, the generally smaller diameter of VAM hyphae (2–4 μ m) compared to root hairs (710 μ m) affords a greater absorptive surface area for hyphae and enables entry of hyphae into soil pores and organic matter that cannot be entered by root hairs (Dodd et al., 2000; Drew et al., 2003).

VAM may chemically modify the rhizosphere through exudation of chelating compounds (Jayachandran et al., 1989; Treeby et al., 1989) or phosphatases (Harley, 1989), which could solubilize poorly soluble soil P. It is clear, however, that VAM utilizes the same sources of P as nonmycorrhizal plants (Mosse et al., 1973; Kucey et al., 1989; Blal et al., 1990), but do so more efficiently.

On a unit weight basis, mycorrhizal plants can rapidly absorb larger amounts of P than nonmycorrhizal plants (Bolan et al., 1987). This difference cannot be accounted for by increased surface area of the hyphae alone; it is, therefore, possible that a greater affinity for P in mycorrhizal plants increased absorption rates. It is also possible that the critical or minimum P concentration, below which there is limited net absorption of P, is lower for mycorrhizal than nonmycorrhizal plants because of an increase in physical contact between hyphae and P, thereby reducing P diffusion distance.

For more detailed information on the role of arbuscular mycorrhizae in influencing soil P availability and plant uptake of P, the reader is directed to the excellent review of Jakobsen et al. (2005).

11.2.5 Optimizing Soil Phosphorus Availability

Critical available soil P concentrations are required to maximize crop yields. These soil concentrations can be optimized by P additions, liming, and cultivation. This section discusses how these factors influence soil P availability; the soil testing and recommendation process that quantifies P additions is discussed in the Chapter 14.

11.2.5.1 Critical Concentrations for Plant Production

Estimates of soil P concentrations, above which little or no crop response to P additions is obtained, vary with the extractant used (Kamprath and Watson, 1980). In many neutral to calcareous soils, 10 mg P kg⁻¹ Olsen P was adequate for wheat, alfalfa, and cotton (Olsen et al., 1954). For Bray-1 P, the critical level is about 30 mg P kg⁻¹ for Midwestern U.S. soils (Thomas and Peaslee, 1973).

Several additional factors influence the availability of soil P. These include temperature, soil compaction, soil moisture, soil aeration, soil pH, type and amount of clay content, and nutrient (including P) status of soil. When soil temperatures are low during early plant growth, P uptake is reduced. Soil compaction reduces pore space, decreasing the amount of water and oxygen, which, in turn, reduces P uptake. The use of liming materials to increase soil pH, and thereby soil P availability, is an old practice,

which has been adequately reviewed by several authors (Adams, 1984; Kamprath, 1984; McLean and Brown, 1984). Reducing subsoil acidity has not been highly successful due to physical limitations of mixing lime into subsoils. However, surface applications of gypsum with sufficient time for transport into the subsoil have been shown to increase crop yields, increase subsoil Ca, and decrease exchangeable Al (Sumner et al., 1986; Farina and Channon, 1988). Soils with high clay content tend to fix more P than sandy soils with low clay content. Thus, more P needs to be added to raise the soil test level of clay soils than loam and sandy soils. In addition, the presence of ammonium enhances P uptake by creating an acid environment around the root when ammonium ions are absorbed. High concentrations of ammonium-N in the soil with fertilizer P may interfere with and delay normal P fixation reactions, prolonging the availability of fertilizer P (Murphy, 1988).

11.2.5.2 Phosphorus Additions

Optimizing soil P availability through P additions should consider application rate, timing, type, placement, and residual availability (Singh and Lal, 2005). Because of the immobility of P in most soils, the timing of fertilizer P application is not as critical as its placement. Even so, small amounts of placed starter fertilizer for vegetable crops have successfully reduced the need for much larger broadcast applications of P (Costigan, 1988), and a similar strategy (e.g., foliar applications) may be appropriate for other crops. In efforts to minimize P inputs in sustainable or low-input management systems, there has been renewed interest in the estimation and utilization of residual P availability from fertilizer or manure amendments (Pierzynski et al., 1990a; Yerokum and Christenson, 1990; McCollum, 1991; Linquist et al., 1997; Oberson et al., 1999; Tiessen, 2005).

11.2.5.2.1 Rate

The application of P either as mineral fertilizer or animal manure increases available soil P (Table 11.4). In many areas of intensive crop and livestock operations, the application of P at rates greater than crop removal has increased available soil P content above critical concentrations for crop production (Kellogg et al., 2000; Kleinman et al., 2005; Lanyon, 2005; Sharpley et al., 2005). The increase in available soil P ranged from 5 to 31 mg kg⁻¹ for every 100 kg ha⁻¹ of fertilizer P added (an average 18% increase; Table 11.4). Barber (1979), Rehm et al. (1984), and McCollum (1991) also observed 13%–28% increases in available P following mineral fertilizer P application. These values are similar to proportional increases following application of beef (7–23 mg kg⁻¹; an average 14%), poultry (14–28 mg kg⁻¹; an average 20%), and swine manure (5–20 mg kg⁻¹; an average 11%) (Table 11.4).

In general, annual applications of manure in crop production systems generally results in crop yields comparable to those obtained with commercial fertilizer, especially when applied based on its N content (Sutton et al., 1982; Lucero et al., 1995; Stevenson et al. 1998; Eghball and Power, 1999; Randall et al., 1999; Schmitt et al., 1999; Macoon et al., 2002). However, long-term N-based applications of manure can result in the

accumulation of available soil P to levels greater than optimum for crop production (King et al., 1990; Sharpley et al., 1993, 2004; Sims et al., 1998; Mullins et al., 2005).

11.2.5.2.2 Type

Traditional soluble P fertilizers are ordinary superphosphate, triple superphosphate, ammonium polyphosphate, monoammonium phosphate, and diammonium phosphate (Young et al., 1985). The use of slow release P fertilizers, such as partially acidulated rock P (RP), on soils other than those with low pH, Ca, and P content have also been evaluated (Hedley et al., 1989; Muchovej et al., 1989). For example, in soils of neutral pH, it may be possible to apply a heavy initial dressing of finely ground RP and include a rotation of fine rooted legumes to generate a low pH rhizosphere with low Ca concentrations and, thus, increase RP dissolution. Other methods designed to increase acidity in the immediate RP-soil environment, and thereby its dissolution, include addition of elemental S (Muchovej et al., 1989), NH₄+ fertilizers, or organic matter such as animal manure and crop residues (Hedley et al., 1989).

Animal manure itself is a valuable resource of P for crop production. The availability of P in manure in some soils may differ from fertilizer P (Table 11.3; Figure 11.4; Hue, 1991; Frossard et al., 1995). As a major proportion of P in manure can be organic (25%–50%), biological processes in soil will play a greater role in determining P availability than for fertilizer P, when applied at equivalent rates of P. In as much, the slower release of P from manure may make it a longer-term source of P to crops than more readily soluble fertilizer P.

Adding manure can cause an increase in soil pH (Kingery et al., 1994; Iyamuremye et al., 1996; Eghball, 2002), due to input of large amounts of Ca (up to 60 g Ca kg manure⁻¹) and the buffering effects of added bicarbonates and organic acids with carboxyl and phenolic hydroxyl groups (Sharpley and Moyer, 2000; Whalen et al., 2000). This suggests that not only the amounts but also form, solubility, and relative availability of soil P for crop uptake and release to overland flow can change with manure application (Wang et al., 1995). In fact, Sharpley et al. (2004) found that the long-term application (10-25 years) of dairy, poultry, or swine manure to 20 sites in New York, Oklahoma, and Pennsylvania resulted in an average increase in soil pH from 5.9 to 6.6, exchangeable Ca from 0.9 to 6.2 g kg⁻¹, organic C from 15.7 to 32.6 g kg⁻¹, and total P from 407 to 2480 mg kg⁻¹, between untreated and treated sites. What was more important to soil P availability was that as Mehlich-3 P increased (22–662 mg kg⁻¹), the proportion that was water soluble (14%-3%) declined as exchangeable Ca increased ($R^2 = 0.81$). Ion-activity products suggested that addition of manure to soil shifts P from Al- and Feto Ca-P reaction products, accounting for the relatively greater Mehlcih-3 P but lower water extractability of soil P (Sharpley et al., 2004). This has important implications for agronomic and environmental soil P testing, where acid-based extractants, such as Mehlich-3 and Bray may dissolve Ca-P complexes in manured soils that may not accurately reflect plant availability or potential for release to runoff. For instance, this may explain

TABLE 11.4 Available Soil P of Soil Treated with Fertilizer or Manure for Several Years and Untreated Soil in the U.S. and U.K. Studies

the plateau in the relationship between Mehlich-3 P and runoff dissolved P observed by Torbert et al. (2002). Thus, at high soils P levels Mehclih-3 P is likely extracting some P that may not be immediately released from manured surface soil to runoff.

11.2.5.2.3 Placement

Due to the general immobility of P in the soil profile, fertilizer placement is generally more critical for P than N. Depending on soil and environmental factors, band applications of P may or may not be better than broadcast incorporated applications of P. The effect of P application also varies with soil type. For six soils having a 100-fold variation in P sorptivity, Holford (1989) found that fertilizer P effectiveness, as measured by yield response in the first crop (wheat), residual effect in the second crop (clover), or cumulative recovery of applied P, was consistently greater for shallow banding at 5cm depth compared to banding at 15cm or broadcast applications. The almost equal effect obtained by mixing P throughout the soil, regardless of P sorptivity, suggested that the positional availability of P in the root zone is important in maximizing fertilizer effectiveness (Holford, 1989) in addition to reducing P sorption.

Positional availability is also influenced by crop type. In order for banding or restricted fertilizer placement to increase potential root extraction of P, the rate of P absorption and growth of roots in fertilized soil must increase to compensate for roots in unfertilized soil. Increased root growth and P uptake in the P-fertilized volume of soil compared to unfertilized soil has been observed for corn (Anghinoni and Barber, 1980), soybeans (Borkert and Barber, 1985), and wheat (Yao and Barber, 1986). In contrast, several studies have shown that flax does not respond to banded fertilizer due to an inability of its root system to expand and proliferate into and efficiently absorb P from high concentrations in the fertilized zone (Soper and Kalra, 1969; Strong and Soper, 1974). In the case of flax, increased P uptake and yield response was obtained when fertilizer P was placed 2–5 cm directly below the seed, ensuring adequate P levels during early growth (Bailey and Grant, 1989).

Field variability in soil properties, crop-yield potential, and topographic differences can affect site-specific requirements of P. For example, mixing a few fertile soil subsamples with any number of subsamples with marginal nutrient availability can produce misleading analytical results. An example from Nebraska, where scientists extensively sampled a 58 ha cornfield, illustrates this situation (Hergert et al., 1994; Peterson et al., 1994). More than 2000 cores collected from a 58 ha cornfield showed that about 75% of the field would likely respond to P fertilization. Yet, composited annual soil samples indicated a need for little, if any, P fertilizer. Further investigation disclosed the existence of an old farmstead that included a swine feeding operation from 20 years earlier and another area where sheep had been fed in confinement more than 70 years ago.

Integration of the spatial variability of soil properties into fertilizer management and placement decisions will receive greater attention as agronomic response models are developed that incorporate the information now readily available through precision agriculture technology. Such technology, coupled with soil and nutrient management information, will facilitate the correct rate and method of N and P application to meet crop needs.

11.2.5.2.4 Residual Availability

Halvorson and Black (1985) showed that soil test P levels were increased above the initial available P level for more than 16 years, by a one-time P application on a Williams loam (*Typic Argiborolls*) in Montana (Figure 11.6). After the initial increase, available P levels declined for about 12 years and then stabilized at a higher available level than was initially present, thus establishing what appears to be a new equilibrium level of available P. Fixen (1986) reported similar changes in available P levels with time. Crop yields, reported by Halvorson and Black (1985), were also improved by the residual P fertilizer for a period of 16 years (Figure 11.6).

The rate of decline in soil P in high P soils when no further P is added varies with soil type and management (Table 11.5). The rate of decline in available soil P ranged from 0.1 to 30 mg kg⁻¹ year⁻¹. McCollum (1991) estimated that without further P, 16–18 years of corn (*Z. mays* L.) or soybean (*G. max* (L.) Merr.) production would be needed to deplete soil P (Mehlich-3 P) in a Portsmouth fine sandy loam (*Typic Umbraquults*) from 100 mg P kg⁻¹ to the agronomic threshold level of 20 mg P kg⁻¹. Several authors have found the rate of decrease in available soil P with depletion by cropping when no P is added is inversely related to the soil's P buffering capacity (Holford, 1982; Aquino and Hanson, 1984; Dodd and Mallarino, 2005) or P sorption saturation (available soil P/P sorption maximum; Sharpley, 1996).

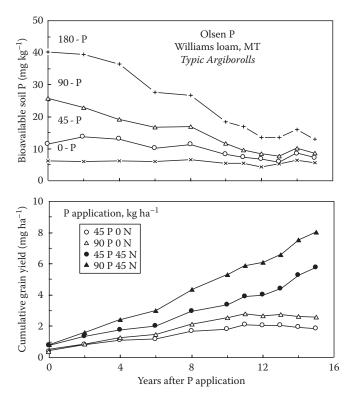

FIGURE 11.6 Changes in bioavailable soil P (Olsen P) and cumulative wheat yields following a single application of fertilizer P. (Data adapted from Halvorson, A.D., and A.L. Black. 1985. Long-term dryland crop responses to residual phosphorus fertilizer. Soil Sci. Soc. Am. J. 49:928–933.)

11.2.5.3 Land Management

11.2.5.3.1 Cultivation

Cultivation and associated fertilizer applications can influence the amount of soil P_i and P_o and should be considered in optimizing soil P availability. Thompson et al. (1954) measured a decrease in P_i and Po content of 25 surface (0-15 cm) soils from Iowa, Texas, and Colorado, with cultivation. Similarly, Adepetu and Corey (1976) reported that 25% of the P_o content of the surface of a Nigerian soil was mineralized during the first two cropping periods following cultivation. In fact, P_i changes little with crop removal and no fertilizer P application, but available P declines gradually. The net loss from the system through removal in the harvested crop is primarily accounted for by a decrease in Po. For example, 60 years (1913-1973) of cotton growth on the Mississippi Delta soil, Dundee silt loam (Typic Endoaqualfs), with no reported P added, resulted in no appreciable effect on P_i (Sharpley and Smith, 1983). However, the P_o content of cultivated (93 mg kg⁻¹) compared to virgin analogue (223 mg kg⁻¹) surface soil (0–15 cm) decreased. Mineralization of P_o slowly replenished the P_i pool, which resulted in a 50% reduction in Bray-1 available P. Where cultivation involved P application, P_i and P_o increased 130% and 227%, respectively, while Bray-1 available P increased 84% and P sorption capacity decreased 33% on an average for 8 U.S. agricultural soils (Sharpley and Smith, 1983).

11.2.5.3.2 Remediation of High P Soils

Large amounts of coal combustion by-products are produced annually by power plants in compliance with clean air legislation (U.S. Environmental Protection Agency, 1988). These by-products can be used safely to increase soil pH and reduce subsoil acidity (Stout and Priddy, 1996; Stout et al., 1999; Callahan et al., 2002). Recent research also suggests that two of these by-products—fluidized bed combustion fly ash and flue gas desulfurization gypsum—can greatly reduce water-soluble P levels in soils and surface runoff without appreciably reducing the plant-available P and plant growth; moreover, heavy metals and arsenic in plants or runoff water are not increased (Stout et al., 1998, 2000).

The use of these amendments on critical areas of a watershed has the potential to make large albeit short-term reductions in P loss (Stout et al., 1999).

11.2.6 Water Quality Implications of Soil Phosphorus Availability

Many studies have reported that the loss of dissolved P in surface runoff is dependent on the available P content of surface soil as measured by soil P test extractants (Sharpley et al., 1996; Pote et al., 1999b; Pierson et al., 2001; Torbert et al., 2002; Andraski and Bundy, 2003; Daverede et al., 2003). For instance, runoff P—soil P relationships were developed within a 40 ha watershed (FD-36) in south-central Pennsylvania (Northumberland Co.), where there was a wide range in soil test P concentration as Mehlich-3 P (20–600 mg L⁻¹) (McDowell and Sharpley, 2001; Sharpley et al., 2001). As Mehlich-3 soil P increased, so did the concentration of dissolved P in surface runoff from 2 m² plots subjected to a 30 min rainfall of 7 cm h⁻¹ (Figure 11.7). Similarly, the concentration of P in subsurface flow is also related to surface soil P (Figure 11.7). Lysimeters of 30 cm depth were taken from

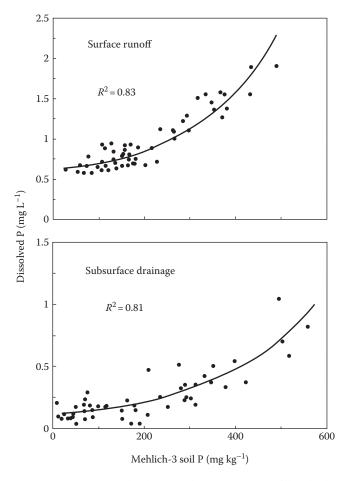

FIGURE 11.7 Relationship between the concentration of dissolved P in surface runoff from $2\,\mathrm{m}^2$ plots and subsurface drainage from $30\,\mathrm{cm}$ deep lysimeters and surface soil (0–5 cm depth) Mehlich-3 extractable P concentration from a central PA watershed.

the same Pennsylvania watershed and subjected to simulated rainfall (1 cm h^{-1} for 30 min). The concentration of dissolved P in drainage from the lysimeter increased (0.07–2.02 mg L^{-1}) as the Mehlich-3 P concentration of surface soil increased (Figure 11.7; McDowell and Sharpley, 2001; Sharpley et al., 2001). The dependence of leachate P on surface soil P is evidence of the importance of P transport in preferential flow pathways such as macropores, earthworm holes, and old root channels.

Vadas et al. (2005) conducted a detailed review of the large amount of research published since the late 1990s on the relationship between soil P availability and runoff dissolved P (Table 11.6). Clearly, there was a range in the extraction coefficient representing the slope of the soil P—runoff P relationship or in more simple terms, the extractability of soil P by runoff water. Significant differences among extraction coefficients were not related to any one soil physical, chemical, or management factor (Vadas et al., 2005). The most likely factor influencing soil P extractability was site hydrology, such that a greater proportion of applied rainfall as runoff translated into more P being desorbed from the surface soil and transported in runoff (Vadas et al., 2005). When these studies were combined to include runoff from soil boxes and field plots that were tilled, notilled, cropped, and grassed, a single extraction coefficient of 2.0 related Mehlich-3 soil P (mg kg⁻¹) to runoff dissolved P (µg L⁻¹).

This information supports the use of soil test P as a measure of soil P availability in estimating the potential for dissolved P enrichment of runoff, as used in nonpoint source models and more recently in estimating the environmental implications of soil P on runoff P, in relation to impairment of surface waters. Thus, as we move from agronomic to environmental concerns with P, where continued applications of P usually as manure, have led to increased available soil P above optimum levels for crop production, soil P testing is being used to indicate when P enrichment of runoff may become unacceptable. Because of this, a common approach has been to use agronomic soil P standards, following the rationale that soil P in excess of crop requirements is vulnerable to removal by surface runoff or leaching. As agronomic standards already exist for soil test P, this approach required little investment in research and development and can be readily implemented. However, we must be careful how we interpret soil test results for environmental purposes (Figure 11.8).

Interpretations given on soil test reports (i.e., low, medium, optimum, high, etc.) are based on expected crop yield response to P and not on soil P release to surface or subsurface runoff (Sharpley et al., 1994). Some have tried to simply extend crop response levels and say that a soil test that is above the level where a crop response is expected is in excess of crop needs and therefore is potentially polluting (Figure 11.8). However, two factors are of critical importance to the debate on how to use soil test P in environmental risk assessment. First, the gap between crop and environmental soil P thresholds reflects the difference in soil P removed by an acid or base extractant (i.e., Mehlich, Bray, Olsen agronomic tests) and by less invasive water (i.e., simulating extraction of soil P by runoff water), which is soil specific. Secondly, soil P is only one of several factors influencing the

TABLE 11.6 Extraction Coefficients Relating Soil P Availability (mg kg⁻¹) to Runoff Dissolved P (DP; µg L⁻¹)

Source: Adapted from Vadas, P.A., P.J.A. Kleinman, and A.N. Sharpley. 2005. Relating soil phosphorus to dissolved phosphorus in runoff: A single extraction coefficient for water quality modeling. J. Environ. Qual. 34:572–580.

Note: fsl, fine sandy loam; fas, sandy loam; sl, silt loam; scl, silty clay loam; cl, clay loam; c, clay.

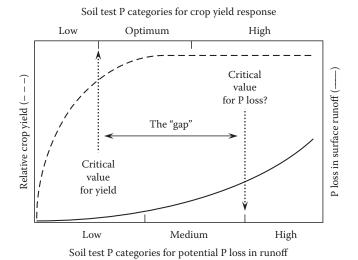

FIGURE 11.8 As soil P increases, so does crop yield and the potential for P loss in surface runoff. The interval between the critical soil P value for yield and runoff P will be important for P management.

potential for P loss; therefore, soil test P should not be used as the sole criteria on which to base P management planning.

11.2.7 Conclusions

The amount and availability of soil P is determined by physical, chemical, and biological processes, which are often managed in attempts to increase or optimize crop uptake of P and yields. In many areas, P cycles have been fragmented by the specialization of agricultural production systems in specific regions. For instance, mineral fertilizer P is imported to areas of crop

production from continental United States and overseas deposits, which have been treated to varying degree to increase P solubility. The harvested grain is used to meet human demands, for animal feed, and more recently as biofuel feedstock. In each case, major population areas, confined animal operations, and biorefineries are geographically removed from areas of crop production. For example, most of the corn produced in the Midwest is used as feed in eastern U.S. states. As a result, P is moving from areas where ore deposits are mined, through crop producing regions, and is accumulating in areas of confined animal operations.

Future management of soil P availability must address the impacts that this specialization of agricultural systems is having on regional P requirements and production on a national scale. At the farm scale, however, efforts should continue to find ways of enhancing the efficient use of P, through soil testing, appropriate rates of P application, and utilization of manure sources of P in an increasing number of agricultural production systems. If these goals are not met, soil P availability may become an environmental rather than fertility issue in more areas.

11.3 Bioavailability of Soil Potassium

Donald L. Sparks

11.3.1 Introduction

The role of K in soils is prodigious. Of the many plant nutrient—soil mineral relationships, those involving K are of major, if not prime, significance (Sparks and Huang, 1985; Sparks, 1999).

Since the middle of the seventeenth century, when J.R. Glauker in the Netherlands first proposed that saltpeter (KNO₃) was the principle of vegetation, K has been recognized as being beneficial to plant growth (Russell, 1961). Glauker obtained large increases in plant growth from the addition of saltpeter to the soil that was derived from the leaching of coral soils. The essentiality of K to plant growth has been known since the work of von Liebig.

Of the major nutrient elements, K is usually the most abundant in soils (Reitemeier, 1951). Igneous rocks of the Earth's crust have higher K contents than sedimentary rocks. Of the igneous rocks, granites and syenites contain 46–54, basalts 7, and peridotites 2.0 g K kg $^{-1}$. Among the sedimentary rocks, clayey shales contain 30, whereas limestones have an average of only 6 g K kg $^{-1}$ (Malavolta, 1985).

Mineral soils generally range between 0.04% and 3% K. Total K contents in soils range between 3000 and 100,000 kg ha⁻¹ in the upper 0.2 m of the soil profile. Of this total K content, 98% is bound in the mineral form, whereas 2% is in soil solution and exchangeable phases (Schroeder, 1979; Bertsch and Thomas, 1985).

Potassium, among mineral cations required by plants, is the largest in nonhydrated size (r = 0.133 nm) and the number of oxygen atoms surrounding it in mineral structures is high (8 or 12), which suggests that the strength of each K–O bond is relatively weak (Sparks and Huang, 1985). Potassium has a polarizability equal to 0.088 nm³, which is higher than for Ca²+, Li+, Mg²+, and Na+ but lower than for Ba²+, Cs+, NH₄+, and Rb+ ions (Rich, 1968, 1972; Sparks and Huang, 1985). Ions with higher polarizability are preferred in ion-exchange reactions. Potassium has a hydration energy of 142.5 kJ g⁻¹ ion⁻¹, which indicates little ability to cause soil swelling (Helfferich, 1962).

11.3.2 Forms of Soil Potassium

Soil K exists in four forms in soils: solution, exchangeable, fixed or nonexchangeable, and structural or mineral (Figure 11.9). Quantities of exchangeable, nonexchangeable, and total K in the surface layer (0–20 cm) of a variety of soils are shown in Table 11.7. Exchangeable K and nonexchangeable K levels comprise a small portion of the total K. The bulk of total soil K is in the mineral fraction (Sparks and Huang, 1985). There are equilibrium and kinetic reactions between the four forms of soil K that affect the level of soil solution K at any particular time and, thus, the amount of readily available K for plants. The forms of soil K in the order of their availability to plants and microbes are solution > exchangeable > fixed (nonexchangeable) > mineral (Sparks and Huang, 1985; Sparks, 1987, 1999).

11.3.2.1 Solution K

Soil solution K is the form of K that is directly taken up by plants and microbes and also is the form most subject to leaching in soils. Levels of soil solution K are generally low, unless recent

amendments of K have been made to the soil. The quantity of K in the soil solution varies from 2 to 5 mg K L⁻¹ for normal agricultural soils of humid regions and is an order of magnitude higher in arid region soils (Haby et al., 1990). Levels of solution K are affected by the equilibrium and kinetic reactions that occur between the forms of soil K, the soil moisture content, and the concentrations of bivalent cations in solution and on the exchanger phase (Sparks and Huang, 1985; Sparks, 1999).

11.3.2.2 Exchangeable K

Exchangeable K is the portion of the soil K that is electrostatically bound as an outer-sphere complex to the surfaces of clay minerals and humic substances. It is readily exchanged with other cations and also is readily available to plants.

11.3.2.3 Nonexchangeable K

Nonexchangeable or fixed K differs from mineral K in that it is not bonded within the crystal structures of soil mineral particles. It is held between adjacent tetrahedral layers of dioctahedral and trioctahedral micas, vermiculites, and intergrade clay minerals such as chloritized vermiculite (Rich, 1972; Sparks and Huang, 1985; Sparks, 1987). Potassium becomes fixed because the binding forces between K and the clay surfaces are greater than the hydration forces between individual K+ ions. This results in a partial collapse of the crystal structures and the K+ ions are physically trapped to varying degrees, making K release a slow, diffusion controlled process (Sparks, 1987). Nonexchangeable K also can be found in wedge zones of weathered micas and vermiculites (Rich, 1964). Only ions with a size similar to K+, such as NH₄+ and H₃O+, can exchange K from wedge zones (Chapter 21 of Handbook of Soil Sciences: Properties and Processes). Large hydrated cations, such as Ca2+ and Mg2+, cannot fit into the wedge zones. Release of nonexchangeable K to the exchangeable form occurs when levels of exchangeable and soil solution K are decreased by crop removal and/or leaching and perhaps by large increases in microbial activity (Sparks, 1980).

Nonexchangeable K is moderately to sparingly available to plants (Mengel, 1985; Sparks and Huang, 1985; Sparks, 1987). Mortland et al. (1956) showed that biotite could be altered to vermiculite by plant removal of K. Schroeder and Dummler (1966) showed that the nonexchangeable K associated with some German soil illites was an important source of K to crops. The ability of plants to take up nonexchangeable K appears to be related to the plant species. Steffens and Mengel (1979) found that ryegrass (Lolium perenne) could take up nonexchangeable K longer without yield reductions, while red clover (Trifolium pratense) could not. This was attributed to the ryegrass having longer root length, which would allow it to grow at a relatively low K concentration. A similar concentration would result in a K deficiency in red clover. It may be that the difference in root mass, root length, and root morphology between monocots and dicots explains why monocots feed better from nonexchangeable K than dicots (Mengel, 1985).

11.3.2.4 Mineral K

As noted earlier, most of the total K in soils is in the mineral form, mainly as K-bearing primary minerals such as muscovite, biotite, and feldspars. For example, in some Delaware soils, Sadusky et al. (1987) found that mineral K comprised about 98% of the total K (Table 11.8). Most of the mineral K was present as K feldspars in the sand fractions.

Common soil K-bearing minerals, in the order of availability of their K to plants, are biotite, muscovite, orthoclase, and microcline (Huang et al., 1968; Sparks, 1987). Mineral K is generally assumed to be only slowly available to plants; however, the availability is dependent on the level of K in the other forms, and the degree of weathering of the feldspars and micas constituting the mineral K fraction (Sparks and Huang, 1985; Sparks, 1987).

 $^{^{\}rm a}$ Data are for surface soils (0–20 cm depth).

TABLE 11.8 Potassium Status of Delaware Soils and Sand Fractions

Source: Sadusky, M.C., D.L. Sparks, M.R. Noll, and G.J. Hendricks. 1987. Kinetics and mechanisms of potassium release from sandy soils. Soil Sci. Soc. Am. J. 51:1460–1465. With permission of the Soil Science Society of America.

Sadusky et al. (1987) and Parker et al. (1989a, 1989b) have found that a substantial amount of K is released from the sand fractions of Delaware soils that are high in K feldspars. This finding, along with the large quantities of mineral K in these and other Atlantic Coastal Plain soils, could help in explaining the often observed lack of crop response to K amendments on these soils (Liebhardt et al., 1976; Yuan et al., 1976; Sparks et al., 1980; Woodruff and Parks, 1980; Parker et al., 1989a).

11.3.3 Factors Affecting Potassium Availability

11.3.3.1 Solution-Exchangeable K Dynamics

The rate and direction of reactions between solution and exchangeable forms of K determine whether applied K will be leached into lower horizons, taken up by plants, converted into unavailable forms, or released into available forms.

The reaction rate between soil solution and exchangeable phases of K is strongly dependent on the type of clay minerals present (Sivasubramaniam and Talibudeen, 1972; Sparks et al., 1980; Sparks and Jardine, 1981, 1984; Jardine and Sparks, 1984) and the method employed to measure kinetics of K exchange (Sparks, 1989, 1995; Amacher, 1991; Sparks et al., 1996). Vermiculite, montmorillonite, kaolinite, and hydrous mica vary drastically in their ionic preferences, ion binding affinities, and types of ion-exchange reactions. Such fundamental differences in these clay minerals account for the varying kinetics of K exchange.

Kinetics of K exchange on kaolinite and montmorillonite are usually quite rapid (Malcolm and Kennedy, 1969; Sparks and Jardine, 1984; Sparks, 1995, 2002). An illustration of this is shown in Figure 11.10. In the case of kaolin clays, the tetrahedral layers of adjacent clay layers are held tightly by H bonds; thus, only planar external surface and edge sites

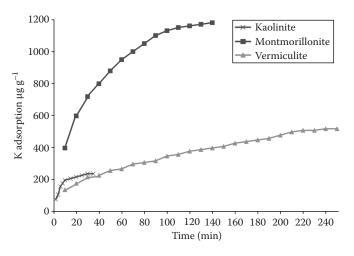

FIGURE 11.10 Potassium adsorption versus time in pure systems. (From Sparks, D.L., and P.M. Jardine. 1984. Soil Sci. 138:115–122. With permission of Wolters Kluwer.)

are available for ionic exchange. With montmorillonite, the inner peripheral space is not held together by H bonds, but instead is able to swell with adequate hydration and thus allow for rapid passage of ions into the interlayer space. Malcolm and Kennedy (1969) found that the rate of Ba exchange on kaolinite and montmorillonite was rapid with 75% of the total exchange occurring in 3 s.

Kinetics of K exchange on vermiculitic and micaceous minerals tends to be extremely slow. Both are 2:1 phyllosilicates with peripheral spaces that impede many ion-exchange reactions. Micaceous minerals typically have a more restrictive interlayer space than vermiculite since the area between layer silicates of the former is selective for certain types of cations (e.g., K⁺, Cs⁺). Bolt et al. (1963) theorized the existence of three types of binding sites

^a Mineral K = [(total K) - (CaCl₂ ext. K + HNO₃ ext. K)].

^b These data represent the amount of total K in the sand based on a whole soil basis.

^c Determined through petrographic analyses of the whole sand fractions and represents the percentage of total point counts in a given sample that were K feldspars. The remaining minerals in the sand fraction were quartz, plagioclase, and opaques.

for K exchange on hydrous mica. The authors hypothesized that slow kinetics were due to internal exchange sites, rapid kinetics to external planar sites, and intermediate kinetics to edge sites.

11.3.3.2 Potassium Fixation

The phenomenon of K fixation or retention significantly affects K availability. The fact that fixation processes are limited to interlayer ions, such as K⁺, has been explained in terms of the good fit of K⁺ ions (the crystalline radius and coordination number are ideal) in an area created by holes and adjacent oxygen layers (Barshad, 1951). The important forces involved in interlayer reactions in clays are electrostatic attractions between the negatively charged layers and the positive interlayer ions, and expansive forces due to ion hydration (Kittrick, 1966).

The degree of K fixation in clays and soils depends on the type of clay mineral and its charge density, the degree of interlayering, the moisture content, the concentration of K⁺ ions as well as the concentration of competing cations, and the pH of the ambient solution bathing the clay or soil (Rich, 1968; Sparks and Huang, 1985).

The major clay minerals responsible for K fixation are montmorillonite, vermiculite, and weathered micas. In acid soils, the principal clay mineral responsible for K fixation is dioctahedral vermiculite. Weathered micas fix K under moist as well as dry conditions, whereas some montmorillonites fix K only under dry conditions (Rich, 1968).

The degree of K fixation is strongly influenced by the charge density on the layer silicate. Those with high charge density fix more K than those with low charge density (Walker, 1957). Weir (1965) noted that K fixation by montmorillonites is limited unless the charge density of the clays is high. Low charge montmorillonite (Wyoming) stays at 1.5 nm when K saturated, unless it is heated (Laffer et al., 1966). Schwertmann (1962a, 1962b) noted that soil montmorillonites have a greater capacity to fix K than do many specimen montmorillonites. Soil montmorillonites have higher charge density and a greater probability of having wedge positions near mica-like zones where the selectivity for K is high (Rich, 1968).

The importance of interlayer hydroxy Al and hydroxy Fe³⁺ material on K fixation was first noted in the classic work of Rich and Obenshain (1955). They theorized that hydroxy Al and hydroxy Fe³⁺ interlayer groups acted as props to decrease K fixation. This theory was later corroborated in the work of Rich and Black (1964) who found that the introduction of hydroxy Al groups into Libby vermiculite increased the Gapon selectivity coefficient (k_G) from 5.7 to 11.1 × 10⁻² L mmol^{-1/2}.

Wetting and drying as well as freezing and thawing can significantly affect K fixation (Hanway and Scott, 1957; McLean and Simon, 1958; Cook and Hutcheson, 1960). The degree of K fixation or release on wetting or drying is dependent on the type of colloid present and the level of K⁺ ions in the soil solution.

Potassium fixation by 2:1 clay minerals may be strongly influenced by the kind of adsorbed cations or the anions within the system. In studies with the silicate ion, Mortland and Gieseking (1951) found that montmorillonite clays dried with K₂SiO₃ were

altered in their swelling properties and fixed K in large amounts. Hydrous mica clays also fixed large amounts of K that could not be removed with boiling HNO_3 .

Volk (1934) observed a marked increase in K fixation in soils where pH was raised to about 9 or 10 with $\rm Na_2CO_3$. Martin et al. (1946) showed that at pH values up to 2.5 there was no fixation; between pH 2.5 and 5.5, the amount of K fixation increased very rapidly. Above pH 5.5, fixation increased more slowly. These differences in K fixation with pH were discussed by Thomas and Hipp (1968). At pH values >5.5, Al³+ cations precipitate as hydroxy polycations, which increase in the number of OH groups as pH increases, until they have a form like gibbsite (Thomas, 1960). At this pH (~8), Al³+ does not neutralize the charge on the clay and cannot prevent K fixation. Below pH 5.5, Al³+ and Al(OH)_x species dominate. Below pH 3.5, $\rm H_3O^+$ predominates (Coleman and Harward, 1953; Thomas and Hipp, 1968).

The increase in K fixation between pH 5.5 and 7.0 can be ascribed to the decreased numbers of $Al(OH)_x$ species, which decrease K fixation (Rich and Obenshain, 1955; Rich, 1960, 1964; Rich and Black, 1964). At low pH, the lack of K fixation is probably due to large numbers of H_3O^+ and their ability to replace K as well (Rich, 1964; Rich and Black, 1964).

11.3.3.3 Potassium Release

The release of K from micas proceeds by two processes: (1) the transformation of K-bearing micas to expansible 2:1 layer silicates by exchanging the K with hydrated cations and (2) the dissolution of the micas followed by the formation of weathering products. The relative importance of these two mechanisms depends on the stability of micas and the nature of soil environments (Sparks and Huang, 1985).

Release of K from feldspars appears to involve a rapid exchange with H, which creates a thin layer of hydrolyzed aluminosilicate. This residual layer ranges in thickness from several to a few tens of nanometers and seems to cause the initial nonstoichiometric release of alkali and alkaline earths, relative to Si and Al. Following this step, there is continued dissolution, which removes hyperfine particles. After these are removed, further dissolution breaks down the outer surface of the residual layer at the same rate that alkalis are replaced by H at the interface between fresh mineral surfaces and the residual layer. This releases all constituents to the solution. Release is now stoichiometric. Thus, the weathering of feldspars appears to be a surface-controlled reaction (Sparks, 1989).

A number of physiochemical and mineralogical factors govern the release of K from micas by both cation exchange reactions and dissolution processes. These include tetrahedral rotation and cell dimensions, degree of tetrahedral tilting, hydroxyl orientation, chemical composition, particle size, structural imperfections, degree of K depletion, layer charge alterations and associated reactions, hydronium ions, biological activity, inorganic cations, wetting and drying, and other factors (Sparks and Huang, 1985). This review will focus on the latter four factors.

Biological activity promotes K release from micas (Mortland et al., 1956; Boyle et al., 1967; Sawhney and Voight, 1969;

Weed et al., 1969). The organisms deplete the K in the soil solution, and their action may be analogous to that of tetraphenylboron (TPB) in artificial weathering of micas. Furthermore, the overall action of organisms is more complex when organic acids are produced (Boyle et al., 1967; Spyridakis et al., 1967; Sawhney and Voight, 1969).

The importance of organic acids in weathering of rock-forming minerals has been recognized for a long time (Sprengel, 1826; Bolton, 1882; Huang and Keller, 1970). All soils contain small but measurable amounts of biochemical compounds such as organic acids. Furthermore, since the time required for soil formation can extend over a period of centuries, the cumulative effect in a soil of even very small quantities of chelating agents will be considerable. The influence of oxalic and citric acids on the dynamics of K release from micas and feldspars was studied by Song and Huang (1988). They found that the sequence of K release from K-bearing minerals by oxalic and citric acids is biotite > microcline orthoclase > muscovite.

The activity of K⁺ ions in soil solution around mica particles greatly influences the release of K from micas by cation exchange. When the K level is less than the critical value, K is replaced from the interlayer by other cations from the solution. On the contrary, when the K level is greater than the critical value, the mica expansible 2:1 mineral takes K from the solution. The critical K level is highly mineral dependent, being much higher for the trioctahedral minerals (Smith and Scott 1966; Newman, 1969; von Reichenbach, 1973; Henderson et al., 1976). The critical levels for muscovite are so low that even the K impurities in laboratory chemicals or dissolved from glassware are often sufficient to prevent any K release (Scott and Smith, 1966).

The nature and concentration of the replacing cations also influences the critical K level of the cations tested in Cl⁻ solutions. Rausell-Colom et al. (1965) found the critical K levels decreased in the order Ba²⁺ > Mg²⁺ > Ca²⁺ \approx Sr²⁺ for the same concentration of these ions and with a constant mica particle size. The activity of all of these replacing ions in the solution phase must be much greater than that of the K for significant K release to occur. The activity of various cations in the soil solution is governed by other minerals in the soil systems, by pedogenic processes, and by anthropogenic activities.

The release of K upon drying a soil is related to the clay fraction (Scott and Hanway, 1960). When a soil is dried, the degree of rotation of weathered soil minerals, such as micas, may be changed. Thus, the K–O bond may be modified. Dehydration of interlayer cations, because Ca could now compete with K for wedge sites. This seems to account for the release of K from soils upon drying. Rich (1972) found that Virginia soils, which contain hydroxy Al interlayers and appreciable amounts of K, did not release K upon drying. The presence of the hydroxy Al interlayers may block or retard the interlayer diffusion of K ions and may change the b-dimension of micas, the degree of tetrahedral rotation, and the length and strength of the K–O bond.

Other factors that can affect K release from soils are leaching, redox potential (Eh), and temperature. Leaching promotes the K

release from K-bearing minerals by carrying away the reaction products. Therefore, leaching accelerates the transformation of minerals, for example, micas, to expansible 2:1 layer silicates and other weathering products if the chemistry of leaching water favors the reaction.

Redox potential of soils could influence K release from micas since it has been pointed out that the tenacity with which K is held by biotite is greater after oxidation of its structural Fe. It appears that, other factors being equal, the extent of the K release from biotite should be less in soil environments that oxidize Fe than in soil environments that reduce it. Major elements in K-bearing feldspars do not exist in more than one valence state; thus, the prevailing Eh of a soil may not be of direct concern to chemical weathering of the feldspars. However, the weatherability of feldspars can be affected by complexing organic acids that are vulnerable to oxidation. Therefore, the stability of feldspars may be indirectly related to the prevailing Eh of a soil.

Increasing temperature has been shown to increase the rate of K release from biotite (Rausell-Colom et al., 1965) and K feld-spars (Rasmussen, 1972). Under conditions of leaching of biotite with 0.1 mol NaCl L⁻¹, the rate of K release appears directly proportional to temperature in the range of 293–323 K (Mortland, 1958). Under similar leaching conditions, Mortland and Ellis (1959) observed that the log of the rate constant for K release from fixed K in vermiculite was directly proportional to the inverse of the absolute temperature.

Preheating of micas to high temperatures (1273 K) prior to TPB extraction (Scott et al., 1973) was found to enhance the rate of K extraction from muscovite, to decrease the rate for biotite, and to have little effect on phlogopite, except at very high temperatures. The decrease in K release from biotite by preheating is presumably because of oxidation of Fe at high temperatures. The more rapid rate with muscovite following heating remains unexplained.

11.3.3.4 Leaching of Potassium in Soils

Soil solution K is either leached or sorbed by plants or soils. A number of factors influence the movement of K in soils, including the cation exchange capacity (CEC), soil pH and liming, method and rate of K application, and K absorption by plants (Terry and McCants, 1968; Sparks, 1980).

The ability of a soil to retain applied K is very dependent on the CEC of the soil. Thus, the amount of clay and SOM in the soil strongly influences the degree of K leaching. Soils with higher CEC have a greater ability to retain added K, whereas leaching of K is often a problem on sandy soils (Sparks and Huang, 1985).

Retention of K can often be enhanced in sandy, Atlantic Coastal Plain soils after application of lime, since in such variable charge soils, the CEC is increased as soil pH is increased. Nolan and Pritchett (1960) found that liming a Lakeland fine sand soil (thermic, coated *Typic Quartzipsamment*) to pH 6–6.5 caused maximum retentivity of applied K. Potassium was replaced by Ca on the exchange complex at higher levels of limestone application. Less leaching of K occurred at pH 6.0–6.5 due to enhanced substitution of K for Ca than for Al, which was more abundant at low pH.

Lutrick (1963) found that K leaching occurred on unlimed but not on limed areas when 112–224 kg K ha⁻¹ was applied on a Eustis loamy fine sand (sandy, siliceous, thermic Psammentic Paleudult).

Movement of applied K has been related to the method of application. Nolan and Pritchett (1960) compared banded and broadcast placement of KCl applied at several rates to Arredondo fine sand (loamy, siliceous, hyperthermic Grossarenic Paleudult) in lysimeters under winter and summer crops. For the low rate of application, cumulative K removal for both placements was only about $5.0\,\mathrm{kg}$ ha⁻¹.

A number of investigations have been conducted to determine the relationship of crop uptake and the rate of K application to leaching of K. Jackson and Thomas (1960) applied up to 524kg K ha⁻¹ prior to planting sweet potatoes (Ipomoea batatas L.) on Norfolk sandy loam (fine loamy, siliceous, thermic Typic Paleudult). At harvest time, soil and plant K exceeded applied K at the 131 and 262 kg K ha⁻¹ rates. However, at the 524 kg K ha⁻¹ rate, 38 kg K was unaccounted for by soil and plant K. This deficiency of K was attributed to leaching below sampling depths. During a 2 year study with corn (Zea mays L.) on two Dothan (Typic Paleudult) soils of Virginia, Sparks et al. (1980) found that 83 and 249 kg of applied K ha-1 increased the exchangeable K in the E and B21t horizons of the two soils. These increases were ascribed to leaching of applied K. The magnitude of leaching varied directly with rate of K application. No accumulation of K was found in the top 0.76 m of Leon sand (sandy, siliceous, thermic Aeric Haplaquod) after 40 year of heavy K fertilization (Blue et al., 1955).

11.3.4 Assessing Potassium Extractability and Availability

The extractability and availability of soil and plant K can be assessed by using chemical extractants to quantify the various forms of soil K, soil test extractants, quantity/intensity (Q/I) analyses, and plant analysis.

11.3.4.1 Chemical Extractants for Soil K Forms

Methods to determine total K and the other alkali elements in soils use acids or a high temperature fusion to decompose the soil. The most widely employed digestion techniques for total elements in soils and minerals have used combinations of HF and either $\rm H_2SO_4$ or $\rm HClO_4$ (Helmke and Sparks, 1996).

Exchangeable K is that K that is typically extracted with a neutral normal salt, usually $1.0\,\mathrm{M}$ NH₄OAc minus the water soluble K (Knudsen et al., 1982). In soils that are not saline, levels of water soluble K are minimal and can be ignored. However, in saline soils, the levels of water soluble K should be determined from a saturated extract or some similar extract and subtracted from the amount of K determined using NH₄OAc.

It should be noted that in soils that contain weathered vermiculitic and micaceous minerals wedge zones can be present that contain K. This K is not accessible to large index cations such as Ca and Mg, but can be extracted by NH₄, which is of similar size to K. For example, in soils that contain wedge zones, NH₄OAc will extract more K than an extractant like 1 M CaCl₂.

It is debatable whether this K is truly exchangeable. Thus, in soils containing wedge zones, exchangeable K could be overestimated with NH₄OAc (Sparks and Huang, 1985; Helmke and Sparks, 1996)

There are a number of chemical methods that can be employed to extract nonexchangeable K. These include boiling HNO₃, H₂SO₄, hot HCl, electroultrafiltration, Na TPB with EDTA, and ion-exchange resins such as H and Ca saturated resins (Hunter and Pratt, 1957; Martin and Sparks, 1985; Helmke and Sparks, 1996).

The most commonly used method for extraction of nonexchangeable K is the boiling HNO₃ technique. Most researchers that use this method boil the soil in M HNO₃ for 10 min over a flame, transfer the slurry to a filter, leach the soil with dilute HNO₃, and then determine the concentration in the filtrate. One of the problems with boiling for only 10 min over a flame is that it is difficult to be precise about the correct boiling time, the time it takes for boiling to occur, and the vigor of boiling (Martin and Sparks, 1985). Some workers have attempted to diminish these problems by using a 386 K oil bath for 25 min, including heating time (Pratt, 1965). This modification is particularly useful when large numbers of samples are being analyzed. Of course, one of the major concerns with using a boiling HNO₃ procedure is the potential to cause partial dissolution of mineral forms of K.

Other researchers have used continuous leaching of the soil with dilute acids such as 0.01 M HCl or with dilute salts such as 0.1 M NaCl, repeated extractions with 3, 0.3, and 0.03 M NaCl, Sr salts, hot $MgCl_2$, and sodium cobaltinitrite (Martin and Sparks, 1985).

Cation-exchange resins saturated with H or Ca also have been widely used to measure nonexchangeable K. These resins have high CECs and when saturated with an appropriate cation and mixed with soil and with a dilute solution, they will adsorb released K. One of the major advantages of using cation-exchange resins to extract K is that they act as a sink for the released K and thus prevent an inhibition of further K release. This is a problem with many batch methods that employ dilute acids and electrolytes. One major disadvantage of cation-exchange resins for extracting K is that the resins are expensive and the procedure is time-consuming and tedious.

In order for electrolyte and acid solutions and cation-exchange resins to be effective in extracting K, the K concentration in the solution phase must be kept very low, or K release must be inhibited (Rausell-Colom et al., 1965; Wells and Norrish, 1968; Feigenbaum et al., 1981; Martin and Sparks, 1983, 1985). The critical concentration above which release is inhibited is 4 mg L⁻¹ for soils in general, 2.3–16.8 mg L⁻¹ for trioctahedral micas in dilute solution, and as low as <0.1 mg L⁻¹ for muscovite and illite (Smith and Scott, 1966; Martin and Sparks, 1985). A low enough concentration of solution K can be maintained by employing a continuous flowing extracting or exchanging solution, cation-exchange resins, or Na TPB (Scott et al., 1960).

One can quantitatively analyze for mineral K (K feldspars and micas) by using a selective dissolution method employing Na₂S₂O₇ fusion. The technique and method for calculating the

quantities of K feldspars and micas can be found in Helmke and Sparks (1996). A semiquantitative approach for measuring mineral K is to subtract the quantity of nonexchangeable K, using the boiling HNO₃ procedure, from the quantity of total K, using the HF digestion method. One also can quantify K feldspars in the sand fraction of soil, using petrographic analyses (Parker et al., 1989b).

11.3.4.2 Soil Tests for Potassium

Soil test extractants for K were developed to easily and rapidly measure K in soils and to estimate K availability. Based on the amounts of extractable K, recommendations that are based on field test calibrations can then be made on the amount of K that is needed to maximize plant yields. Soil tests for K usually estimate the quantity of solution and exchangeable K, and since acids are usually employed as extractants, some nonexchangeable and mineral K is also extracted (Wolf and Beegle, 1991). The soil tests used to measure extractable K in the United States include Mehlich-1 and Mehlich-3 procedures in the northeastern and southeastern United States, the Morgan and modified Morgan procedures in parts of the northeastern United States, the 1 M NH₄OAc at pH 7 procedure in the north-central United States, and the ammonium bicarbonate-DTPA extraction in the western United States. Procedures for these soil tests are fully described in Helmke and Sparks (1996) and Chapter 14.

11.3.4.3 Q/I Analysis

Schofield (1947) proposed that the ratio of the activity of cations such as K and Ca was defined by the relation $a_{\rm K}/(a_{\rm Ca})^{1/2}$ where a is the ion activity. He appears to have been the first person to apply the concepts of quantity (Q) and intensity (I) to the mineral nutrient status of soils (Schofield, 1955).

Beckett (1964a), following the consideration of the Ratio law (Schofield, 1947), suggested that the I of K in a soil at equilibrium with its soil solution could best be defined by the ratio $a_{\rm K}/(a_{\rm Ca}+a_{\rm Mg})^{1/2}$ of the soil solution. This equilibrium activity ratio for K or $AR^{\rm K}$ (Beckett, 1964a) has often been used as a measure of K availability to plants (Sumner and Marques, 1966; le Roux and Sumner, 1968).

Beckett (1964c) suggested that exchangeable K is held by two distinct mechanisms. The majority is held by general force fields comparable with those that hold exchangeable Na or Ca. A small proportion is held at sites offering a specific binding force for K but not for Ca and Mg. The electrochemical potential of exchangeable K in the diffuse double layer dictates the chemical potential of K in the soil solution. The K activity is also affected by the difference in electrical potential across the diffuse double layer that surrounds the exchange complex. Thus, no simple relationship exists between the activity of K in soil solution and quantity of K on the exchange phase (San Valentin et al., 1973). Moss (1967) and Lee (1973) note that a soil with a given complement of exchangeable K, Ca, and Mg gives rise to an activity ratio for $K(AR^{K})$ in the equilibrium soil solution that will be characteristic of that soil and independent of the soil-to-solution ratio and total electrolyte concentration. Moss (1967) noted that the ratio depends only on K saturation and the strength of adsorption of cations.

However, the relation of the amount of exchangeable K to $AR^{\rm K}$ must be specified to accurately describe the K status of a soil. Beckett (1964b) noted that different soils showing the same value of $AR^{\rm K}$ may not possess the same capacity for maintaining $AR^{\rm K}$ while K is removed by plant roots. Therefore, one must include not only the current potential of K in the labile pool but also the form of Q/I or the way in which potential depends on quantity of labile K present. These findings brought about the classic Q/I curves where the ratio of $a_{\rm K}/(a_{\rm Ca}+a_{\rm Mg})^{1/2}$ is related to the change in exchangeable K to obtain the effect of quantity (exchangeable K) on intensity. The Q/I concept has been widely promulgated in the scientific literature to investigate the K status of soils (Evangelou et al., 1994).

The traditional method for Q/I analyses involves equilibrating a soil with solutions containing a constant amount of CaCl, and increasing the amounts of KCl (Beckett, 1964a). The soil gains or loses K to achieve the characteristic AR^K of the soil or remains unchanged if its AR^{K} is the same as the equilibrating solution. The AR^K values are then plotted versus the gain or loss of K to form the characteristic Q/I curve. From the Q/I plot, one can obtain several parameters to characterize the K status of a soil. The AR^K when the Q factor or ΔK equals zero is a measure of the degree of K availability at equilibrium or AR_e^K . The value of ΔK when $AR^K = 0$ is a measure of labile or exchangeable K in soils (ΔK°). The slope of the linear portion of the curve gives the potential buffering capacity of K (PBCK) and is proportional to the CEC of the soil. The number of specific sites for K (K_x) is the difference between the intercept of the curved and linear portion of the Q/I plot at $AR^K = 0$ (Beckett, 1964b; Sparks and Liebhardt, 1981; Evangelou et al., 1994).

The traditional method described above is too time-consuming for routine analyses. Advances in ion-selective electrode (ISE) technology have allowed for more rapid Q/I analysis (Evangelou et al., 1994). Parra and Torrent (1983) developed an ISE simplified Q/I method whereby a single K-ISE in an electrochemical cell with liquid junction was employed to quantitate the K concentration (C_K) in equilibrated soil suspensions based on a successive addition procedure. The values of AR^{K} were estimated based on the expression, $AR^{K} = (11.5 - 0.3b) C_{K} + 22 \times 10^{-6}$, where b is the CEC (cmol_c kg⁻¹) based on the weight of the soil samples used. The method of Parra and Torrent (1983) is quicker than the traditional Q/I method because equilibration time is reduced to 10 min compared to 24h for the traditional method. Parra and Torrent (1983) achieved results with their modified procedure that were comparable to the traditional method. Wang et al. (1988) modified the procedure of Parra and Torrent (1983) by making direct measurements of CR_K (concentration ratio: $C_K/(C_{Ca+Mg})^{1/2}$) values with Ca and K-ISEs in an electrochemical cell with or without liquid junction.

11.3.4.4 Plant K Analysis

Plant K analysis will not be discussed in any detail in this review. For extensive discussions on plant analysis, the reviewer

Crop	Time of Sampling	Plant Part	Critical Concentration ^a
Sugarbeet		Blade	10
Cotton		Leaves	<9-15
Wheat	Jointing (GS6)	Total tops	20-25
	Early boot (GS9)	Total tops	15-20
Rice	Flag leaf to mid-tillering		10-14
Corn	At tassel	Ear leaf	19
	At tassel	Leaves	17-27
	At silk	Sixth leaf from base	13
	At silk	Leaf opposite and just below ear shoot	20
Grain sorghum	Full heading	Second blade below apex	18
Alfalfa		Whole top	8-22
Red clover		Tops	15-22.5
Bermudagrass		Tops	13-15
Orchardgrass		Tops	23-25
Tall fescue		Tops	24-38
Kentucky bluegrass		Tops	16-20

TABLE 11.9 Critical K Concentrations in Agronomic Crops

Source: Westerman, R.L. (ed.). 1990. Soil testing and plant analysis. SSSA, Madison, WI. With permission of the Soil Science Society of America.

is referred to chapters in Westerman (1990). Table 11.9 lists the critical level or concentration of K for various agronomic crops. These levels are usually determined by relating yield (e.g., percentage of the maximum yield or growth rate) to nutrient concentration (g kg-1) for a specific plant part sampled at a given stage of development (Munson and Nelson, 1990). This method is based on the principle that if an element such as K is deficient in a plant, growth rates and yield will be decreased. If one adds increasing amounts of K, the concentration of the element in the plant or plant part increases until an optimum level is attained. Using this approach, growth or yield is expressed as a percentage of the maximum. The zone between the deficient and optimum concentration can be referred to as the transition zone (Ulrich and Hills, 1967). Ulrich and Hills (1967) referred to the transition zone as the zone between nutrient concentrations that produced a 20% reduction in growth or yield and continues to those that cause optimum or 100% in the maximum yield. Dow and Roberts (1982) refer to this latter zone as the critical range where researchers select the yield reduction and nutrient concentrations that are acceptable.

11.4 Bioavailability of Calcium, Magnesium, Sulfur, and Silicon

James J. Camberato William L. Pan

11.4.1 Introduction

Calcium, Mg, and S are essential mineral elements that are classified as macronutrients. While these three elements generally accumulate in plant tissues in higher concentrations (1.5–35 g kg⁻¹) (Table 11.10) than the micronutrients, they are not as commonly limiting in crop production as N, P, and K. Yet, when the soil bioavailability of Ca, Mg, and S is low, crop yield and quality can be suboptimal, depending on crop species and environmental conditions. Although Si is an essential element in the classical sense for diatoms and algal species of the genera Chrysophyceae and Equisetaceae (Epstein, 1999), it is considered a "beneficial" or "quasiessential" element for many other plant species, most notably rice (*Oryza sativa* L.) and sugarcane (*Saccharum officinarum* L.) (Epstein, 1994).

TABLE 11.10 Calcium and Magnesium Concentrations in Plant Tissue Considered Adequate for Plant Growth

		Range of Concentration				
		Ca	Mg	S		
Plant	Tissue		g kg ⁻¹ Tissue			
Maize	Ear leaf	2.1-10.0	2.0-4.0	1.2-2.5		
Rice	Leaves (tillering)	1.6-3.9	1.6-3.9	0.9-3.8		
Wheat	Leaves (heading)	2.0-5.0	1.5-5.0	1.5-4.0		
Soybean	Leaves	3.6-20.0	2.6-10.0	2.0-4.0		
Peanut	Leaves and stem	7.5-20.0	3.0-7.5	2.0-3.0		
Cotton	Leaves	19.0-35.0	3.0-7.5	2.9-15.0		
Fruit trees	Leaves	14.0-21.0	4.1-6.8	1.3-3.0

Adams (ed.), Soil Acidity and Liming, SSSA, Madison, WI, 1984, pp. 99–170; S data compiled from Asher, C.J. et al., Sulfur nutrition of tropical annual crops, in G.J. Blair and A.R. Till (eds.), Sulfur in South East Asian and South Pacific Agriculture, The University of New England, Armidale, New South Wales, Australia, 1983, pp. 54–64; Fox, R.L. and Blair, G.J., Plant response to sulfur in tropical soils, in M.A. Tabatabai (ed.), Sulfur in Agriculture, ASA, Madison, WI, 1986, pp. 405–434; Kamprath, E.J. and Jones, U.S., Plant response to sulfur in the Southeastern United States, in M.A. Tabatabai (ed.), Sulfur in Agriculture, ASA, Madison, WI, 1986, pp. 323–343; Jones, M.B., Sulfur availability indexes, in M.A. Tabatabai (ed.), Sulfur in Agriculture, ASA, Madison, WI, 1986, pp. 549–566; Tiwari, K.N., Sulphur Agric., 14, 29, 1990.

The bioavailability of Ca, Mg, S, and Si is governed by the following factors: (1) parent material, (2) ion-exchange reactions, (3) biological transformations, (4) losses from the crop root zone by leaching and crop removal from the field, and (5) replenishment via atmospheric deposition, fertilizer, and soil amendments. Factors influencing Ca and Mg bioavailability are collectively discussed due to the similarity in soil chemical and plant nutritional behavior of these two elements. In contrast, S and Si chemistry in soils and plant nutrition are distinctly different, and are discussed separately in the latter half of the section.

11.4.2 Calcium and Magnesium

11.4.2.1 Overview of Calcium and Magnesium Nutrition

General reviews of the function of Ca and Mg in plants have been written by Clark (1984), Hanson (1984), and Poovaiah and Reddy (1996). A large proportion of Ca is found as Ca pectates in cell walls for structural rigidity, or as Ca oxalate and other organic acids in the apoplasm or vacuoles (Kinzel, 1989; Borchert, 1990). Calcium functions in plants include maintenance of membrane integrity (Caldwell and Haug, 1981) and cell wall stability (Konno et al., 1984), root (Poovaiah and Reddy, 1996) and shoot (Slocum and Roux, 1983) gravitropism, callose deposition (Lerchl et al., 1989), and regulation of several enzymes including α -amylase (Mitsui et al., 1984), protein kinases (Raghothama et al., 1987), and ATPases (Clarkson and Hanson, 1980).

Magnesium functions as an enzyme activator, in addition to serving as the coordinating central cation in the chlorophyll molecule. Magnesium activates numerous plant enzymes by bridging enzymes with ligand groups of substrates to optimize geometric conformation of enzyme systems involving the transfer of phosphate or carboxyl groups (Marschner, 1995). Systems activated by Mg include chlorophyll biosynthesis (Walker and Weinstein, 1991), chlorophyll degradation (Langmeier et al., 1993), photosynthesis (Pierce, 1986), protein synthesis (Cammarano et al., 1972), ATP synthesis (Lin and Nobel, 1971), and ATPases (Balke and Hodges, 1975), some of which are involved in phloem loading of sucrose (Williams and Hall, 1987).

11.4.2.2 Occurrence of Soil Calcium and Magnesium

Calcium and Mg occur in soils primarily in mineral forms and as ions on the exchange complex or in the soil solution. Little Ca or Mg occurs in organic complexes in soils (Mokwunye and Melsted, 1972). The relative amounts of Ca derived from parent materials rank as follows: calcareous sedimentary rock > basic igneous rock > acid igneous rock (Jenny, 1941). Parent materials rank with respect to Mg contents: basic igneous rock > acid igneous rock > sedimentary rock (Metson, 1974). Generally, soils with the highest 2:1 lattice clay content have the highest Mg contents (Mokwunye and Melsted, 1972). Contents of Ca and Mg in soils are presented in Table 11.11.

TABLE 11.11 Contents of Calcium and Magnesium in Various Soils

	'	Content			
	Ca	Mg	Source		
Soil Type		(g kg ⁻¹	1)		
Temperate soils	0.7-36	1.2-15	Brady (1974)		
Humid region soil	4	3	Brady (1974)		
Arid region soil	10	6	Brady (1974)		
Peat soils	1.1-48.3		Brady (1974)		
Muck soils		0.7-5.7	Millar (1955)		

11.4.2.3 Additions and Losses of Soil Calcium and Magnesium

Calcium and Mg accession by soils from atmospheric deposition may be significant in comparison to that removed in crop and forest plants (Johnson and Todd, 1987). Calcium and Mg depositions from precipitation in a Tennessee forest were 6.3 and 0.7 kg ha⁻¹ year⁻¹, respectively (Johnson and Todd, 1987). Hedin et al. (1994) estimated atmospheric Ca depositions for Sweden, the northeastern United States, and the Netherlands in the 1990s to be 0.5, 1.0, and 4.2 kg Ca ha⁻¹ year⁻¹, respectively. Atmospheric deposition of Mg and Ca has garnered more interest lately because of its potential to increase soil inorganic C and thereby reduce atmospheric CO₂ and global warming. Goddard et al. (2007, 2009) reported the highest deposition in the United States to be 1.0–1.4 kg Mg ha⁻¹ year⁻¹ in the Pacific Northwest and coastal Florida and to be 2.5–3.6 kg Ca ha⁻¹ year⁻¹ in the central Midwest–Great Plains region.

Considerable amounts of Ca and Mg are added to soils in the form of limestone (21%–32% Ca, 3%–12% Mg), fertilizers, and animal manures. Fertilizers used to specifically supply Ca to soils include gypsum (22% Ca) and calcium nitrate (19% Ca). Calcium may also be added to the soil incidentally while supplying P as superphosphates (14%–20% Ca). Common Mg-containing fertilizers include Epsom salts (10% Mg) and sulfate of potash magnesia (11% Mg).

Loss of Ca and Mg from the soil occurs through leaching and crop removal. Leaching losses of Ca and Mg from an aspen forest (Populus tremuloides Michx.) on Typic Fragiochrept soils averaged 39 and 9 kg ha-1 year-1, respectively (Silkworth and Grigal, 1982). Cropping with perennial species reduces leaching losses in comparison to annuals. Calcium and Mg leaching losses were 193 and 104 kg ha⁻¹, respectively, from a continuous maize (Zea mays L.) rotation but only 64 and 48 kg ha-1 from a bluegrass (Poa pratensis) sod (Bolton et al., 1970). The application of Ca generally increases the leaching of Mg (Pratt and Harding, 1957), partly because the adsorption affinity for Ca is greater than that for Mg in non-vermiculitic soils (Hunsaker and Pratt, 1971). Leaching of Ca and Mg is accelerated by acidification, resulting from the nitrification of ammoniacal N sources (Schwab et al., 1989; Darusman et al., 1991). Under acid conditions, Al3+ and H+ ions displace Ca2+ and Mg2+ from the exchange complex enabling leaching to occur.

Plant removals of Ca and Mg from the soil are dependent on the plant species and genotype and the harvested fraction that is removed from the field. The Ca concentration of plants varies considerably, but one generalization can be made: the Ca concentration of dicots, legumes, and crucifers (12-18 g kg⁻¹) is far greater than the 4 g kg-1 Ca typically found in grasses (Parker and Truog, 1920). In contrast, the Mg concentration of these groups of plants differs only slightly (~2–4 g kg⁻¹). Several authors have provided compilations of plant mineral composition that may be useful in estimating crop removal of Ca and Mg (Truog, 1918; Beeson, 1941). Magnesium removals were 5, 7, 8, and 16kg Mg ha-1 for snap beans (Phaseolus vulgare L.), okra (Hibiscus esculentus L.), white potatoes (Solanum tuberosum L.), and sweet potatoes (Ipomoea batatas (L.) Lam.), respectively (Prince, 1951). More recently, representative uptakes and removals of Ca and Mg for several crops were reported by Buo1 (1995). Crop removal was in the range of 1-30 kg Ca or Mg ha-1 year-1. Spring wheat (Triticum aestivum L.) accumulated 35 kg Ca ha⁻¹ and 13 kg Mg ha-1, whereas sugar beets (Beta vulgaris L.) accumulated 104 kg Ca ha⁻¹ and 44 kg Mg ha⁻¹ (Strebel and Duynisveld, 1989). Barber (1984) reported the total uptake of Mg by maize to be 45 kg ha⁻¹.

Hardwood tree species accumulate substantial amounts of Ca. For example, a mixed oak (*Quercus* sp.) stand grown on *Typic Paleudult* soils contained 1090 kg Ca ha⁻¹ (16 kg Ca ha⁻¹ year⁻¹) in the aboveground plant parts when harvested (Johnson and Todd, 1987). Loblolly pine (*Pinus taeda* L.) grown on the same soils removed only 196 kg Ca ha⁻¹. Both species removed about 45 kg Mg ha⁻¹ from the soil (0.6 and 1.5 kg Mg ha⁻¹ year⁻¹ for mixed oak and pine, respectively). In a more temperate climate, aspen removed 1034 kg Ca ha⁻¹ and 95 kg Mg ha⁻¹ from *Typic Fragiochrept* soils in northeastern Minnesota (Silkworth and Grigal, 1982).

11.4.2.4 Factors Affecting Availability of Soil Calcium and Magnesium

The activities of Ca and Mg in the soil solution, which directly influence the rates of uptake into plant roots, are dependent on the level of exchangeable cations (Albrecht, 1941) and the type of colloid. Organic matter and 1:1 clays retain Ca less tightly than 2:1 clay minerals, resulting in greater Ca availability at any given level of Ca saturation (Allaway, 1945; Mehlich and Colwell, 1945; Mehlich, 1946).

The affinity of cations for the exchange complex is dependent on the mineralogy of the colloid. For instance, the affinities of Ca and Mg for montmorillonite are similar, but the affinity of Mg for vermiculite is much greater than the affinity of Ca (Wild and Keay, 1964). Soils with exchange complexes arising from organic matter, peat, allophane, kaolinite, and oxides of Fe and Al have a higher affinity for Ca than for Mg (Hunsaker and Pratt, 1971).

The relative abundance of basic cations on the exchange complex affects the plant availability of these ions. Bear et al. (1945) asserted that the ideal base saturation of the exchange complex was 65% of Ca, 10% of Mg, and 5% of K. This concept was termed the basic cation saturation ratio. Although this ideology of soil test interpretation was widely adopted in the Midwestern

United States for making fertilizer and lime recommendations (McLean and Brown, 1984), subsequent research demonstrated that a fairly broad range of basic cation saturations would produce equivalent crop yields (Hunter, 1949; Giddens and Toth, 1951; Key et al., 1962; Simson et al., 1979; Osemwota et al., 2007).

The degree of Ca saturation needed to provide sufficient plantavailable Ca to crops is dependent on the colloid. Kamprath (1984) concluded from the results of a number of studies that a Ca saturation of about 25%-30% and an exchangeable Ca level of 1.0 cmol_c kg⁻¹ in highly weathered soils, dominated by kaolinitic clays and Fe/Al oxides, were adequate for supplying the Ca requirement of most plants. However, other factors such as Al may still limit plant growth at this level of Ca saturation. Soil solution Ca levels in acid soils ranging from 0.38 to 9.3 mM were reported by Kamprath (1978). The soil solution Ca level required for optimum growth of tropical legumes was 0.125 mM, much lower than the 2.0 mM required by temperate legumes (Kamprath, 1978). The soil solution Ca concentration necessary for maximizing cotton (Gossypium hirsutum L.) root growth was between 0.04 and 0.34 mM (Howard and Adams, 1965; Adams and Moore, 1983).

11.4.2.5 Calcium and Magnesium Soil-Plant Relationships

The transport of Ca and Mg ions to the root surface occurs by mass flow and diffusion. The soil solution composition and transpiration have been used to estimate the contribution of mass flow to the movement of these ions to plant roots (Barber, 1962). The difference between total nutrient accumulation in the plant and the estimate of that supplied by mass flow gives the relative contribution of diffusion and root interception. From these estimates, Barber (1962) recognized that mass flow could supply more than the required amount of Ca to plant roots of some soil-plant systems, resulting in a buildup of Ca in the rhizosphere that was observed in subsequent experiments (Barber and Ozanne, 1970). He also surmised that in situations where plant Ca demand is high and soil solution Ca is low, the supply of Ca to plant roots can be diffusion limited (Barber, 1962), resulting in a depletion of soluble Ca around the roots (Barber and Ozanne, 1970). Similarly, the mode of Mg transport is cropping system dependent. While mass flow could account for the Mg accumulated by wheat, a majority of Mg moving to sugar beet roots occurred by diffusion (Strebel and Duynisveld, 1989).

The presence of Ca is required throughout the root profile to maintain the integrity of root cell membranes and nutrient uptake (Haynes and Robbins, 1948). Insufficient Ca limits rooting into the subsoil of many Ultisols (Adams and Moore, 1983) and Oxisols (Ritchey et al., 1982) limiting the volume of soil explored and crop access to soil moisture supplies (Sumner et al., 1986; Sumner, 1995). Subsoil horizons in these soils may also be Al and H toxic (Adams and Moore, 1983). The Ca concentration of the soil solution needed to obtain maximum soybean (*Glycine max* (L.) Merr.) root growth increases as pH decreases and Al activity increases (Lund, 1970). The Ca/Al molar ratio of the

soil solution was determined to be an excellent indicator of the potential for Al stress in tree species (Cronan and Grigal, 1995).

The effects of liming on soil Ca levels are initially confined to the zone of incorporation (Ritchey et al., 1980; Pavan et al., 1984, 1987). However, gypsum, phosphogypsum, and soluble Ca applications are effective at providing Ca deep into the soil profile. Forty-four weeks after application, soil Ca was increased in the upper 20 cm of a tropical Inceptisol, but phosphogypsum and CaCl₂ increased exchangeable Ca to a depth of 80 cm (Pavan et al., 1987). Growth of alfalfa (*Medicago sativa* L.) was increased in an Appling coarse sandy loam (*Typic Hapludult*) by a surface application of gypsum, which increased subsoil Ca and decreased soluble Al (Sumner et al., 1986; Sumner and Carter, 1988; Sumner, 1995).

Low supplies of Ca inhibit the nodulation, growth, and N fixation of bacteria associated with the roots of legumes (Albrecht, 1931; McCalla, 1937). No N fixation occurs unless the Ca saturation is >40% (Albrecht, 1937). The number of nodules and the amount of N fixed increased to 97% Ca saturation. The number of nodules per plant was positively correlated with the total Ca content of the primary root (Sartain and Kamprath, 1978). The Ca requirement for nodulation is greater at low pH and greater than that for the host plant (Alva et al., 1990). Calcium concentration of 0.5 mM maximized nodule number and weight at pH > 5, but 2.5 mM Ca was required at pH 4.5.

The ratio of Ca and Mg to other cations in the soil solution is important in Ca and Mg sufficiency to the plant. Maximum root length of cotton occurred when the activity of Ca exceeded approximately 15% of the total cation activity in the soil solution (Adams, 1966) and when exchangeable Ca was 13% or more of the total exchangeable cations (Howard and Adams, 1965; Adams and Moore, 1983). These relationships were nearly identical for the two soils examined even though the clay mineralogy of one soil was kaolinitic and that of the other was vermiculitic. Other crops respond similarly to the relative activity of Ca in the soil solution. Root growth of soybean (Lund, 1970) and loblolly pine (Lyle and Adams, 1971) were maximized when the ratio of Ca activity to total cation activity in the soil solution exceeded 10%-20%. Magnesium activity expressed as a function of total cation activity in the soil solution was closely correlated with ryegrass (Lolium perenne L.) Mg concentration (Salmon, 1964).

Calcium has low phloem mobility, which results in low Ca redistribution from older plant tissues to growing meristems (Jeschke and Pate, 1991), thereby imposing heavy reliance on concurrent Ca uptake and xylem transport to support new growth and development of vegetative and reproductive tissues (Morard et al., 1996). Plant organs with low rates of transpiration (e.g., new leaves, fruits, tubers) and low rates of xylem flow exhibit Ca deficiency disorders such as pod rot in peanut (*Arachis hypogaea* L.) (Cox et al., 1982; Sumner et al., 1988), internal brown spot in potato (Tzeng et al., 1986), blossom end rot in tomato (*Lycopersicon esculentum* Mill.) (Geraldson, 1957), bitter pit in apple (*Malus* sp.) (Perring, 1986), cork spot in pear (*Pyrus communis* L.) (Raese and Drake, 1993), and blackheart in celery (*Apium graveolens* L.) (Geraldson, 1954). Although low

soil Ca levels may increase the frequency and severity of Ca deficiency in these crops, the deficiency is more a function of poor Ca translocation within the plant than of low soil Ca levels.

Calcium uptake and translocation occur at greater rates in actively growing meristematic regions than older root sections (Clarkson, 1984; Marschner, 1995). As a result, soil Ca availability must be optimized in the root zone at the time of active root development (Kratzke and Palta, 1986). Since environmental stresses that curtail root meristematic development can inhibit Ca uptake and translocation to shoot meristems, temperature and moisture stresses can exacerbate low soil Ca availability by imposing transient Ca deficiencies during critical periods of crop development. These environmental stresses by soil–Ca interactions explain why these Ca-related disorders are only displayed in some growing seasons. Foliar and fruit sprays, as well as maintenance of adequate soil Ca, are required to completely alleviate Ca deficiency disorders in sensitive crops (Geraldson, 1954, 1957; Raese and Drake, 1993).

11.4.2.6 Crop Response to Calcium and Magnesium Availability

Optimum soil Ca levels for maximizing yield and quality of peanuts are quite high, 538 kg ha⁻¹ for small-seeded cultivars, and 1600 kg ha⁻¹ for large-seeded cultivars (Walker et al., 1979; Gaines et al., 1989). Adsorption of Ca for kernel development occurs through the shell. Small-seeded cultivars have relatively more surface area per unit mass for Ca adsorption than large-seeded cultivars, hence the lower soil Ca requirement (Sumner et al., 1988). Reduced peanut yield and quality with low soil Ca are, partly due to destruction of pods by *Pythium* and *Rhizoctonia* fungal pathogens (Hallock and Garren, 1968).

Low Mg uptake by forage grasses can induce grass tetany in ruminants (Grunes et al., 1970), while low Ca in wheat forage leads to wheat pasture poisoning (Bohman et al., 1983). Low rates of Mg and Ca uptake due to suboptimal soil Mg and Ca availability can be exacerbated by high K (Thill and George, 1975; Ohno and Grunes, 1985), low soil temperatures (Miyasaka and Grunes, 1990), low P availability (Reinbott and Blevins, 1994), and wet soil conditions (Karlen et al., 1980). A survey of the incidence of grass tetany in the United States showed greater appearance of the problem in areas where soil parent material is naturally low in Mg and in cooler climates (Kubota et al., 1980). This study concurred with earlier findings of a greater incidence of grass tetany when the Mg concentration in forages is < 2.0 g Mg kg⁻¹ and the K/(Ca + Mg) equivalent ratio is > 2.2 (Kemp and 't Hart, 1957).

Exchangeable Mg levels are often poorly related to crop yield response to applied Mg. Incongruities between exchangeable Mg and crop response primarily arise from two sources: a pool of available Mg in the A horizon soil that is not exchangeable, and an accumulation of available Mg below the A horizon. Nonexchangeable Mg may be an important source of plant-available Mg in some soils. Prince and Toth (1937) noted that only about 3%–4% of the total Mg content of Sassafras loam soil was exchangeable, suggesting fixation of Mg in an insoluble form in

the colloidal fraction of the soil. Substantial plant uptake of non-exchangeable Mg occurred in five Coastal Plain soils where only 4%–9% of the total Mg content was in the exchangeable form (Rice and Kamprath, 1968). An additional 4%–10% of the total soil Mg content was extractable with dilute acid and was termed nonexchangeable, but plant available.

Significant fixation of Mg occurred in Oxisols and Ultisols when limed to pH above 7 (Sumner et al., 1978; Grove et al., 1981). Magnesium fixation was nearly 80% in a Bradson soil (*Typic Hapludult*) limed to a pH of 7.2 (Grove et al., 1981). Subsurface accumulations of Mg may also satisfy crop requirements for Mg. Adams and Hartzog (1980) noted that Mg accumulated in the subsoil of Ultisols could explain the lack of crop growth response to applied Mg on soils with extremely low exchangeable Mg in the topsoil. Exchangeable Mg levels were 10-fold greater in the subsoil (60–120 cm) of Wagram loamy sand (Arenic Kandiudult) than in the surface 40 cm (Schmidt and Cox, 1992).

Magnesium deficiencies are intensified by high levels of K or Ca (Welte and Werner, 1963). Severe Mg deficiency of potato and tobacco (Nicotiana tabacum L.) and mild Mg deficiencies of sugar beet and barley (Hordeum vulgare L.) occurred with heavy applications of K, even though exchangeable Mg levels were considered adequate (Walsh and O'Donohoe, 1945). Magnesium deficiency of citrus occurred when the Mg:K ratio was less than 2.5:1 (Pratt et al., 1957). Magnesium deficiency of alfalfa occurred when Mg comprised <6% of the exchangeable cations (Prince et al., 1947). Similarly, Mg deficiency of sudangrass (Sorghum sudanense [Piper] Stapf) and clover (Trifolium repens L.) occurred when soils had <4% of the CEC occupied by Mg (Adams and Henderson, 1962), and in citrus when Mg was <4%-8% of the CEC (Martin and Page, 1969). Exchangeable Mg in excess of 10% of the CEC generally ensures that Mg availability to crops will not be limiting.

When Mg fertilizer applications are made to the soil surface, as in orchards or pastures, or to crops with high Mg requirements, high-solubility fertilizers are more effective than low-solubility materials (Boynton, 1947; Camp, 1947). For example, MgSO₄ and MgO increased grapefruit (*Citrus paradise* Macfad.) leaf Mg and alleviated visual symptoms of Mg deficiency within 9 months, whereas effects of MgCO₃ were not detected for more than 24 months (Koo, 1971). McMurtrey (1931) reported that considerably more dolomitic limestone was needed than soluble Mg fertilizer to prevent Mg deficiency in tobacco. Foliar applications of MgSO₄ can be more effective than soil applications of Mg deficiency (Scott and Scott, 1951).

11.4.3 Sulfur

11.4.3.1 Overview of Sulfur Nutrition

Sulfur functions in plants have been reviewed by Duke and Reisenauer (1986), DeKok et al. (1993), and Marschner (1995). Sulfur is a structural constituent of organic compounds, some of which are uniquely synthesized by plants, providing animals with essential amino acids (methionine and cysteine) required

to synthesize S-containing proteins. Disulfide bonding plays an important role in regulating the 3D conformation of proteins, affecting enzyme function. Sulfur is also contained in vitamins and coenzymes (thiamin, biotin, coenzyme A, and lipoic acid) (Mengel and Kirkby, 1982; Marschner, 1995). Other S-containing compounds include glutathione, an antioxidant (Bergmann and Rennenberg, 1993), and phytochelatin (Grill et al., 1987) as well as glucosinolates, which can serve as natural plant protectants (Schnug, 1993).

11.4.3.2 Occurrence of Soil Sulfur

Soil S exists in organic compounds, and adsorbed and soil solution SO₄²⁻. Temperate region soils ordinarily contain between 0.1 and 2.0 g S kg⁻¹ (Brady, 1974). Representative soils from arid regions contain more S than those from humid regions (0.8 and 0.4 mg kg⁻¹, respectively) (Brady, 1974). The predominant mineral form of S in arid soils is gypsum. Organic S comprises most of the S in most soils (>90% of the total) (Table 11.12). The C:S and N:S ratios of mineral soils vary. The organic pool is composed of three major sources of S (ester sulfates, amino acid S, and C bonded S). Ester sulfate is considerably more labile than C bonded S and is considered an important source of plant-available S. Ester sulfate and C bonded S accounted for 53% and 14% of total organic S, respectively, in 48 surface soils of Ghana (Acquaye and Kang, 1987). Ester sulfate ranged from 35% to 52% of total S in 54 Canadian soils (Bettany et al., 1973), from 20% to 65% in 6 Brazilian soils, and 43% to 60% in 6 Iowa soils (Neptune et al., 1975). Commonly, more than 30% of the total organic S in soils is not identified as either ester sulfate or C bonded S (Neptune et al., 1975; Acquaye and Kang, 1987). Amino acid S has been reported to account for 21%–31% of the total organic S content of two Australian soils (Freney et al., 1972) and 19%-31% of C bonded S in four mineral soils of Scotland (Scott et al., 1981).

Adsorbed SO₄²⁻ occurs on the positively charged exchange sites at the edges of clay minerals, organic matter, and Fe and Al oxides (Chao et al., 1962). The SO₄²⁻ adsorption capacity of a soil is decreased by increased soil pH and P content (Ensminger, 1954;

TABLE 11.12 Total-S, Organic-S, and C:N:S Ratio of Selected Mineral Soils

	Total-S	Organic-S

 $^{^{\}mathrm{a}}$ Organic C and S for all entries. Total N for all entries, except organic-N for Bettany et al. (1973).

Kamprath et al., 1956). Ultisols, Alfisols, and Oxisols have a high adsorption capacity due to an abundance of Fe and Al oxides and typically low pH. Binding is due to both electrostatic attraction and ligand exchange mechanisms (Marsh et al., 1987; Marcano-Martinez and McBride, 1989) and is highly dependent on the occurrence of positive charge on the soil colloids. Sulfate adsorption occurs rapidly, with nearly complete adsorption in minutes (Rajan, 1978) to days (Marcano-Martinez and McBride, 1989). However, a slower second stage of SO₄²⁻ adsorption also exists, rendering initially adsorbed SO₄²⁻ less available over time (Barrow and Shaw, 1977). Sulfate retention in acid soils is enhanced by Ca (Barrow, 1972; Ryden and Syers, 1976). Marcano-Martinez and McBride (1989) proposed that the stimulation in SO₄ adsorption arose from the bonding of a SO₄-Ca complex to the oxide surface by an O ligand and attraction of the Ca to a negatively charged hydroxyl.

11.4.3.3 Additions and Losses of Sulfur

Major sources of atmospheric S are oceans (24% of the total), soils (35%), volcanic activity (7%), and industry (35%) (Noggle et al., 1986). Sulfur accretion in soils occurs through direct adsorption of S gases and as rainfall. Distance from the source of S determines the amount of deposition. Sulfur in rainfall in Hawaii was exponentially related to distance from the ocean, averaging from 24 to 1 kg S ha-1 year-1 from the coast to 24 km inland (Hue et al., 1990). As much as 168 kg S ha-1 was deposited on soils near industry, whereas urban and rural locations generally received <15 kg S ha-1 (Olson and Rehm, 1986). However, clean air legislation in the United States has substantially decreased S emissions from electric utilities and industrial boilers lowering S deposition >30% in the Northeast and Midwest (USEPA, 2010). Although industrial S emissions continue to be reduced in many industrialized countries, thus reducing S deposition (Schnug, 1991), S deposition in some countries remain quite high (Wang et al., 2004). Areas distant from the sea and devoid of industrial sources may have rainfall concentration of <0.1 mg L⁻¹ (<0.1 kg S ha-1 per 100 mm rainfall) (Fox and Blair, 1986).

The replacement of ordinary superphosphate (12% S) with concentrated superphosphate (1% S) beginning in the late 1940s as the most common P source resulted in an increase in the occurrence of crop S deficiencies in the southern United States (Mehring and Lundstrom, 1938; Jordan, 1964). The use of gypsum as a Ca source for peanuts is another example of incidental S applications to soils. Nutritive applications of S are most frequently applied with N sources. The primary source of S in both liquid and solid N fertilizers is ammonium sulfate (24% S). Ammonium bisulfite (32% S) and thiosulfate (26% S) are also used to provide S in liquid fertilizers. Sulfur sources used in solid fertilizers are potassium sulfate (18% S), potassium magnesium sulfate (23% S), magnesium sulfate (14% S), and ordinary superphosphate. Elemental S is also used sometimes as a slow release source of nutritive S. The S becomes available to plants when the elemental S is oxidized by bacteria to SO₄²⁻ (Starkey, 1966). Oxidation rate is dependent on the size of the S particles, temperature, and moisture (Burns, 1967).

The retention of fertilizer S in surface soils is dependent on rainfall. Nearly 50% of the SO₄²⁻ added to maize was lost from the soil profile by leaching in the subhumid savannah of West Africa (1500 mm rainfall), whereas 100% of that added to a soil in the semiarid savannah (640 mm rainfall) remained in the soil profile to a depth of 105 cm (Friesen, 1991). Nearly all of 56 kg SO₄²⁻ added to Wagram loamy sand (Arenic Paleudult) was leached from the upper 0.45 m of soil with 445 mm of rainfall in 180 days (Rhue and Kamprath, 1973). Leaching losses (24 kg S ha⁻¹ year⁻¹) exceeded crop removal (15 kg S ha⁻¹ year⁻¹) even with S inputs from the atmosphere, crop seed, and fertilizer of 37 kg S ha⁻¹ year⁻¹ and rainfall of 660 mm year⁻¹ in clay loam *Typic Eutrochrept* in central Sweden (Kirchmann et al., 1996). Liming and P fertilization decrease S adsorption and increase SO₄-S leaching (Bolan et al., 1988).

Crop removal of S varies by species. Cruciferous forages, alfalfa, and rapeseed (*Brassica napus* L.) accumulate large amounts of S, about 70 kg S ha⁻¹ (Spencer, 1975). Sugarcane, coffee (*Coffea arabica* L.), and coconut (*Cocos nucifera* L.) accumulate moderate amounts of S (50 kg S ha⁻¹) (Spencer, 1975), while field crops and forages accumulate between 20 and 30 kg S ha⁻¹ annually (Hoeft and Fox, 1986; Kamprath and Jones, 1986).

11.4.3.4 Factors Affecting the Availability of Soil Sulfur

Sulfate uptake by plants from the rooting solution can be saturated at relatively low concentrations of ${\rm SO_4}^{2-}$. Soybean growth was optimized with 0.23 mM ${\rm SO_4}$ -S in nutrient solution (Elkins and Ensminger, 1971). Wheat achieved maximum S accumulation at 0.01 mM ${\rm SO_4}$ -S in solution (Reisenauer, 1969), while Fox and Blair (1986) concluded that approximately 0.14 mM ${\rm SO_4}$ -S was required in the soil solution to optimize growth of some tropical and subtropical crops. Early growth of eight agronomic crops was maximized at 0.06 mM in nutrient solution (Hitsuda et al., 2005). Soil reactions that buffer ${\rm SO_4}^{2-}$ concentrations above these critical soil solution levels are required to optimize S availability. Replenishment of ${\rm SO_4}^{2-}$ in the soil solution from organic and adsorbed sources is important in determining S supply to the plant (Ribeiro et al., 2001).

Extractable S fluctuates during the year. Tan et al. (1994b) reported that SO_4^{2-} and C-bonded S were inversely related throughout the year in three New Zealand pasture soils (Inceptisols), with the highest proportions of C-bonded S occurring in the winter and SO_4 -S predominating in the spring. Although Watkinson and Kear (1996b) found SO_4 -S to be constant throughout the year, in contrast to Tan et al. (1994b), they found extractable organic S concentrations to increase in the fall and winter in agreement with the prior study. Conservation tillage was suspected of limiting organic S mineralization in a silt loam Mollisol, resulting in S deficiency of maize (Rehm, 2005).

Sulfate adsorption is negligible in surface soils because little adsorption occurs at soil pH and phosphate levels conducive to crop plant growth (Kamprath et al., 1956). Therefore, most of the effective SO_4^{2-} adsorption in cultivated soils occurs in acid argillic horizons, which often retain enough S to support plant

growth. The range in water soluble SO₄-S concentrations of surface horizons of Ultisols was 0.09–0.16 mM and in the argillic horizon, 0.20–0.36 mM (Camberato and Kamprath, 1986). The depth of the argillic horizon, in part, determines the plant availability of S accumulated in that soil layer. When the argillic horizon was >0.45 m deep, S fertilization increased the yield of tobacco in 2 of 10 site years on four Ultisols, but S deficiency did not occur when the argillic horizon was within 0.30 m of the soil surface (Smith et al., 1987). Linear decreases in maize earleaf S occurred as depth to the argillic horizon in two Ultisols increased from 0.2 to 1.0 m (Cassel et al., 1996).

The depth of crop rooting also influences the amount of S accessible to the crop in soils with subsoil accumulations of SO_4^{2-} . The amount of SO_4 -S available to tobacco increased during the growing season and was greater than that of cotton on Durham coarse sandy loam soil (Paleudult) with <18 kg SO_4 -S ha⁻¹ in the upper 0.45 m of soil, but >72 kg SO_4 -S ha⁻¹ below 0.45 m (Kamprath et al., 1957). Differences in rooting between these crops explained the difference in S supply. Tobacco was previously shown to have 20% of its root activity below 0.45 m at 7 weeks after transplanting, whereas cotton had a much shallower root system with only 2% of its root activity at this soil depth 11 weeks after planting.

If root growth is prevented by impeding soil layers or high Al³⁺ levels, response to S may occur on soils with high levels of subsoil SO_4^{2-} . Failure to disrupt the tillage pan in a *Typic Kandiudult* prevented rooting into an SO_4^{2-} rich subsoil, and wheat grain yield was increased by S fertilization (Oates and Kamprath, 1985). On an adjacent soil that was subsoiled to allow rooting below the tillage pan, wheat obtained sufficient S for maximum crop productivity. Aluminum saturations in excess of 50% were implicated in reducing rooting in the SO_4^{2-} rich subsoil of Aquic Hapludult, resulting in an increase in maize yield with S fertilization (Kline et al., 1989). Limited crop rooting due to shallow soils causes S deficiency of maize and alfalfa in the Midwestern United States (Hoeft and Fox, 1986).

Sulfur commonly limits crop production in the subhumid and humid regions of the Pacific Northwest. Low atmospheric deposition of S (6 kg ha⁻¹ year⁻¹), low S-containing surface irrigation water and basalt, granite, and volcanic ash parent materials have resulted in soils that have low total S content and low S bioavailability (Rasmussen and Kresge, 1986). Sulfur responses in cereals are dependent on having adequate N availability (Koehler, 1965) and high yield potential (Ramig et al., 1975). High rainfall and winter leaching potential in the humid regions of the Western coastal areas coupled with low S deposition create S deficient conditions in cereal, forage, fruit, and vegetable production (Rasmussen and Kresge, 1986). In contrast, arid soils in the western United States with high accumulations of soluble SO₄²⁻, low leaching potential under nonirrigated conditions, or that are irrigated with high SO₄2--containing groundwater respond less frequently to S fertilization.

11.4.3.5 Assessing Levels of Soil Sulfur

Although organic S is the predominant form of S in most soils, many studies have demonstrated that total S or organic S are

poorly correlated to crop response to applied S. Measures of extractable S, which may include soil solution, exchangeable, and organically bound SO₄²⁻ and S, have been reasonably successful at predicting response to S fertilization. Differences in the chemical extractant, concentration, temperature, and other procedural factors affect the quantity and form of S extracted from the soil (Anderson et al., 1992). The analytical procedure used to determine S in the extract also influences the quantity of S measured. Turbidimetric and anion-exchange chromatography methods measure only solution SO₄²⁻ levels, whereas inductively coupled argon plasma spectrophotometry measures total S in solution, including solution SO₄²⁻, ester SO₄²⁻, and soluble organic S (Anderson et al., 1992). The contribution of S in rainfall to the crop (Hoeft et al., 1973) and subsoil SO₄²⁻, which are not often quantified, may also be reasons why soil S analysis for predicting crop response is not always reliable. An S deficiency risk index based on atmospheric deposition, annual rainfall and soil type, texture, and pH agreed well with the occurrence of reported S deficiency in cereals (McGrath and Zhao, 2007).

Extractable SO₄-S was not a good indicator of S sufficiency on seven silt loam Mollisols in Minnesota (O'Leary and Rehm, 1991). However, the amount of S mineralized during a 4 or 12 week aerobic incubation was related to maize yield response to S fertilization, indicating the importance of organic S to plantavailable S in some soils. Approximately 30% of the S extracted from eight field-moist New Zealand soils was in the soluble organic form, while the remainder was SO₄²⁻ (Tan et al., 1994a). Labile organic-S determined S availability in Oxisols with low and medium S adsorption capacity (SAC), but mineral SO₄-S forms determined S availability in high SAC soils (Ribeiro et al., 2001). Extractable organic S is a good predictor of the amount of labile S. Organic S extracted by potassium phosphate was a better predictor of maximum yield in pastoral soils of New Zealand than initial SO₄²⁻; SO₄²⁻ mineralized during shortterm incubation, organic S extracted by calcium phosphate, or organic S extracted by sodium bicarbonate (Watkinson and Kear, 1996a). Potassium phosphate extracted more organic S from high organic matter soils than the commonly used calcium phosphate extractant. Blair et al. (1991) found that extraction with KCl was superior to either calcium phosphate or sodium bicarbonate as an indicator of pasture response to fertilizer S in 18 soils from northern New South Wales, Australia. Critical levels for the three extractants ranged from 6.5 to 8.4 mg kg⁻¹. The bicarbonate extractant in this case was probably inferior to the others because it overestimated the contribution of available S arising from the ester SO₄²⁻ fraction.

11.4.3.6 Crop Response to Sulfur Availability

Sulfur deficiencies occur worldwide, but are most prevalent in areas where S accretions from atmospheric deposition, the S contents of fertilizers and pesticides, and irrigation water are low, and soils are sandy with low soil organic matter content, and rainfall is plentiful (Tisdale et al., 1986).

Numerous examples of crop S deficiencies and responses to S fertilization are presented by Tabatabai (1986). Recently, the

incidence of S deficiency appears to be increasing in the United States as a result of less atmospheric S deposition. Sawyer et al. (2009) in Iowa noted only 3 S deficiencies out of 200 research trials with maize and soybean in 40 years prior to 2005. Since then, about two-thirds of more than 50 maize and of 6 alfalfa trials have responded to S fertilization (Sawyer et al., 2009). Many years of cropping without S fertilization may also contribute to the increased occurrence of S deficiency.

Sulfur deficiencies decrease crop yields and in certain instances also reduce crop nutritional value and quality. Sulfur fertilization of subirrigated meadow vegetation (Nichols et al., 1990) and forage maize (O'Leary and Rehm, 1990) increased dry matter accumulation, but did not affect crop quality. In other instances, S fertilization increased both the protein- and S-containing amino acid content of forages, resulting in increased animal performance (Rendig, 1986). In mixed pastures, S application up to 90 kg S ha⁻¹ increased total forage production and the proportion of clover to grass (Jones, 1964). Numerous yield responses of coastal bermudagrass (*Cynodon dactylon* (L.) Pers.) to S fertilization have been documented (Kamprath and Jones, 1986). Alfalfa is the most S responsive crop grown in the Midwest and Northeast regions of the United States (Hoeft and Fox, 1986).

Cyst(e)ine and methionine levels of seeds are increased by S fertilization resulting in more nutritious foods (Rendig, 1986). Baking quality of wheat flour is highly dependent on the S concentration of the grain and is increased by S fertilization (Haneklaus et al., 1992). The S status (Zhao et al., 1995) and baking quality (Zhao et al., 1999) of British wheat decreased substantially in the 12 years after 1981 due to reduced atmospheric S deposition. Bread dough made from S-deficient grain resists extension and has lower extensibility (Moss et al., 1981), which is related to low albumin proteins (Wrigley et al., 1984). Sulfur-containing metabolites influence the flavor of several crops including asparagus (Asparagus officinalis L.) and various Allium sp. (Schnug, 1990).

11.4.4 Silicon

11.4.4.1 Overview of Silicon Nutrition

The roles of Si in plant nutrition and agriculture have been recently reviewed in Datnoff et al. (2001), Korndörfer and Lepsch (2001), Ma et al. (2001), and Snyder et al. (2007). Uptake of Si(OH)₄ (Lewin and Reimann, 1969) appears to be active in Si accumulators such as rice, sugarcane, and bamboo [Sasa veitchii (Carrière) Rehder], and passive in others such as oats (Avena sativa L.) and other "dryland" Gramineae (Jones and Handreck, 1967), while legumes and other dicots appeared to exclude Si(OH)₄. Although concentrations of Si in normal plants range from 1 to 100 g kg⁻¹ of dry weight (Epstein, 1999), those in Si accumulators greatly exceed the levels of any essential plant nutrients taken up from the soil (e.g., >200 g Si kg⁻¹ dry weight in mature bamboo leaves [Motomura et al., 2002]). Silica gel (hydrated amorphous silica, SiO₂·nH₂O) is present as specialized "skeletal" structures in the epidermal cells and cell walls of

many plants (Lewin and Reimann, 1969). These structures when enhanced by Si fertilization may be responsible for increased resistance to plant diseases and insect pests. Solid silica in plant tissue occurs as opal (Jones et al., 1966) in the form of phytoliths, which persist in soil after plant decay.

11.4.4.2 Occurrence of Soil Silicon

Silicon, next to $\rm O_2$, is the most abundant element in soils, ranging from 2% to 45% and averaging about 31% in the conterminous United States (Shacklette and Boerngen, 1984). Commonly occurring Si minerals include quartz, tridymite, cristobalite, and inorganic and biogenic opal with solubilities ranging from 1 to 70 mg L $^{-1}$ (Wilding et al., 1977). The Si:O ratio is 1:2 in these minerals. Silicon is also a component of other primary and secondary minerals and of the phyllosilicate clay minerals. Silicon occurs in the soil solution as Si(OH) $_4$ at 0.1–0.6 mM levels (Epstein, 1999).

Silicon bioavailability in soil is primarily a function of Si quantity and solubility as determined by weathering and soil pH. Si(OH)₄ reacts with Fe, Al, Mn, and other heavy metals to form sparingly soluble silicates (Snyder et al., 2007). Si(OH)₄ is sorbed by Fe and Al oxides with the latter sorbing more Si than Fe oxides (Jones and Handreck, 1965). Sorption by both sesquioxides increases with increasing pH (Beckwith and Reeve, 1963; McKeague and Cline, 1963b; Jones and Handreck, 1965). Thus, Si(OH)₄ in the soil solution decreases as pH rises (Beckwith and Reeve, 1963, 1964; McKeague and Cline, 1963a, 1963b; Jones and Handreck, 1965). Flooding increases soil solution Si(OH)₄, probably due to the reduction of Fe, which releases adsorbed Si(OH), (Savant et al., 1997b). Carbonates also sorb Si but not as strongly as sesquioxides (Beckwith and Reeve, 1963). Across 23 paddy soils in China available Si was positively correlated with pH, silt, clay, and CaCO3 content of the soil and negatively correlated with organic matter and amorphous Fe oxide (Liang et al., 1994).

Leaching of Si(OH)₄ from the soil profile is a characteristic of soil weathering. Little Si is accrued in soil via atmospheric deposition, but substantial additions may be realized with irrigation. In Hawaii, rainfall and mist Si concentrations were 0.2 and 0.05 mg L⁻¹, respectively, whereas well water contained between 2.5 and 30 mg Si L⁻¹ (Fox et al., 1967). From a survey of the literature (Savant et al., 1997a), irrigation water Si concentrations ranged from ~2 to 16 mg Si L⁻¹.

11.4.4.3 Crop Response to Silicon Bioavailability

Silicon application increases crop resistance to disease organisms and insect pests while increasing yield. Rice, sugarcane, and barley show the most consistent response to increased Si bioavailability (Snyder et al., 2007). Beneficial responses occur most often on organic soils (Histisols), highly weathered soils (Ultisols and Oxisols), and sandy Entisols (Datnoff and Rodrigues, 2005).

Silicon increases plant resistance to abiotic stresses including moisture deficit, high temperatures, and salinity (Ma, 2004), while it suppresses several diseases of rice including blast (*Magnaporthe grisea*), brown spot (*Cochliobolus miyabeanus*), and stem rot (*M. salvanii*) (Datnoff and Rodrigues, 2005).

Datnoff (2005) summarized the beneficial effects of Si fertilization in reducing several diseases affecting both warm- and cool-season turfgrasses. Pathogens suppressed include *Bipolaris cynodontis*, *M. grisea*, *Pythium aphanidermatum*, *Rhizoctonia solani*, *Sclerotinia homeocarpa*, and *Sphaerotheca fuliginea*. Reynolds et al. (2009) summarized the indirect and direct impacts of Si augmentation of plants on herbivorous insects. Increased plant Si impacts several insect feeding guilds including lepidopteran borers, folivores, and phloem- and xylemfeeders. Silicon applied to the plant foliage also increased plant resistance to some insect pests (Reynolds et al., 2009).

Yield increases in rice due to Si application ranged from 10% to 30% (Savant et al., 1997b); while in China, wheat was less responsive (4%–9%) than rice (5%–21%) (Liang et al., 1994). These beneficial responses in both crops were partly due to reduced diseases and lodging. Sugarcane responses to Si fertilization in Florida, Hawaii, and Mauritius (Matichenkov and Calvert, 2002) ranged from 17% to 30% in total dry matter and 23% to 58% in sucrose content. Beneficial effects were due to increased disease-, pest-, and frost-resistance. Responses of barley to Si in Russia and England (Snyder et al., 2007) were generally in the range of 10%–20%, but several exceeded 40%.

Slags produced from various metal smelters are often used as sources of Si for crop production. Slag composition can be quite variable in Si concentration ranging from 5%–10% in steel mill to 15%–20% Si in blast furnace slags from pig iron manufacture as well as in other essential elements including Ca, Mg, Mn, and Fe (Savant et al., 1997b). Solubility of Si in slag varies widely (–20% to \sim 70%) (Savant et al., 1999) with finer particles being more effective than larger pellets as a source of Si for increasing rice plant tissue Si and reducing disease incidence (Datnoff et al., 1992).

Silicon application rates needed to optimize crop yield are substantially higher than those of any other essential plant nutrient. For example, recommended Si fertilization rates (as Ca silicate slag) to optimize rice yield in Florida are $1500\,\mathrm{kg}$ Si ha⁻¹ at a soil test of <6 mg L⁻¹ soil and 1120 kg Si ha⁻¹ at 6-24 mg L⁻¹ soil (Korndörfer et al., 2001). Suggested rates of slag application for sugarcane production range from 1 to 9 Mg ha-1 (approximately 200-1800 kg Si ha-1), dependent on the slag and soil Si concentration (Savant et al., 1999). The high rates of Si application needed to optimize plant bioavailability arise as a result of reduced solubility in the "fertilizer" material, sorption by the soil, and the large quantity needed by the plant. Although significant residual effects of a single Si application have been observed over 5 years of cropping, 50%-75% of that applied was unavailable after 5 years as assessed by chemical and biological techniques (Khalid and Silva, 1978; Khalid et al., 1978), suggesting transformation into unavailable forms. In another study, the residual value of a 3 Mg Si ha-1 application for reducing disease and increasing of rice yield in the second growing season was approximately equivalent to 1 Mg Si ha⁻¹ applied in that season (Datnoff et al., 1991). Because Si uptake may be as high as 700 kg ha⁻¹ for sugarcane, 300 kg ha⁻¹ for rice, and 150 kg ha⁻¹ for wheat (Snyder et al., 2007), crop removal substantially reduces soil Si (Savant et al., 1997a).

Several soil testing methods to evaluate soil Si sufficiency typically remove a fraction of sorbed Si in addition to water soluble Si. The chemical extractant, solution pH, ionic strength, shaking time, and soil:solution ratio vary among methods and remove different amounts of Si from the soil (Savant et al., 1999). For example, water, phosphate-acetate, acetate, and modified Truog ($\rm H_2SO_4$) methods were evaluated as potential soil test methods for identifying Si deficient soils for sugarcane production (Fox et al., 1967) with critical values being 9, 50, 20, and 40 mg kg⁻¹, respectively. Although each method extracted different amounts of Si, all methods were equally effective in predicting plant Si accumulation (r > 0.92).

11.5 Bioavailability of Micronutrients

Nanthi Bolan

Ravi Naidu

Ross Brennan

Dedik Budianta

Malcolm E. Sumner

11.5.1 Introduction

Minor or trace elements include both biologically essential (e.g., Cu, Mn, Fe, B, Ni, Mo, Cl, and Zn) and nonessential (e.g., Pb, Cd, and Hg) elements. The essential elements (for plant, animal, or human nutrition) are required in low concentrations and hence are known as "micronutrients" (Table 11.13). Because the nonessential minor elements are phyto- and/or zootoxic even at low concentrations, they are widely known as "toxic elements" or

 TABLE 11.13
 Sources of Micronutrients in Soils and Their Functions in Plant and Animal

Micronutrient	Ionic Species in Soil Solution	Sources	Functions
Boron (B)	H ₃ BO ₃ °	Fertilizers, rocks, fly ash	Plant: required for cell wall strength and development, cell division, fruit and seed development, sugar transport, and hormone development
Chloride (Cl)	Cl-	Muriate of potash, micas, feldspars	Plant: controls opening and closing of stomata, balances K in cells, required in photosynthesis, for ionic balance and transport, reduces susceptibility to disease
Cobalt (Co)	Co ³⁺ , Co ²⁺ , [Co(H ₂ O) ₆] ²⁺ ; [CoCl ₄] ²⁻	Fertilizers, mafic rock, minerals	Plant: required for N fixation, stem and coleoptiles elongation, leaf disc expansion, curvature of slit stems, opening of hypocotyl hooks, and bud development Nonenzymatic: Cobalamine or vitamin B12—erythropoiesis, granulopoiesis, glucose homeostasis
Copper (Cu)	Cu ²⁺ , Cu(OH) ₂ °, CuOH ⁺ , CuSO ₄ °, CuCO ₃ °, Cucl ⁺ , CuHCO ₃ ⁺	Fertilizers, fungicides, electrical, paints, pigments, timber treatment, mine tailings	Plant: enzyme activator, major function in: photosynthesis, reproductive stage, respiratory enzymes, indirect role in chlorophyll production, increases sugar content, intensifies color, and improves flavor in fruits and vegetables. Animal: Enzymatic: Cytochrome oxidase—Principal terminal oxidase; Lysyl oxidase—Lysine oxidation; Tyrosinase—Skin pigmentation—Cytocuprein: Superoxide $({\rm O_2}^-)$ dismutation. Nonenzymatic: Growth promoter in swine and poultry; lameness control in cattle
Iron (Fe)	Fe ²⁺ , FeCl ⁺ , Fe(OH) ₂ ⁺ , Fe H ₂ PO ₄ ⁺ , Fe(OH) ₃ ⁻ , Fe (SO ₄) ₂ ⁻ , Fe(OH) ₄ ²⁻	Fertilizers, iron core, rocks, minerals	Plants: Promotes formation of chlorophyll, enzyme mechanism operates the respiratory system of cells, reactions involving cell division, energy transfer within the plant, a constituent of certain enzymes and proteins, plant respiration, and plant metabolism, and involved in N fixation
Manganese (Mn)	Mn ²⁺ , MnOH ⁺ , MnCl ⁺ , MnCO ₃ °, MnHCO ₃ ⁺ , MnSO ₄ °	Fertilizer, rocks	Plant: role in metabolism of organic acids, activates the reduction of nitrite and hydroxylamine to ammonia, role in enzymes involved in respiration and enzyme synthesis, activator of enzyme reactions such as oxidation/reduction, hydrolysis and direct influence on sunlight conversion in the chloroplast, assimilation of carbon dioxide in photosynthesis, synthesis of chlorophyll and in nitrate assimilation, manganese activates fat forming enzymes, formation of riboflavin, ascorbic acid, and carotene, electron transport during photosynthesis, and involved in the Hill Reaction where water is split during photosynthesis Animal: Enzymatic: Arginase—Urea formation; Pyruvate carboxylase—Pyruvate metabolism
Molybdenum (Mo)	MoO ₄ ²⁻ , HMoO ₄ ⁻ , H ₂ MoO ₄ °	Fertilizer	Plant: essential for N fixation and nitrate reduction, converting nitrate into amino acids, conversion of inorganic P into organic forms within the plant Enzymatic: Xanthine oxidase—Purine metabolism; Sulfite oxidase— Sulfite oxidation
Nickel (Ni)	Ni ²⁺ , NiSO ₄ °, NiHCO ₃ +, NiCO ₃ °	Alloys, batteries, mine tailings	Plant: required for Fe absorption, participate in N metabolism of legume during the reproductive phase of growth, phytoalexin synthesis, and plant disease resistance Nonenzymatic: Increases bone strength in poultry
Selenium (Se)	HSeO ₃ ⁻ , SeO ₄ ²⁻ , SeO ₃ ²⁻ , MgSeO ₄ °,	Fertilizers, selenide minerals, recycled electronic devices, sulfide ore	Plant: increases the tolerance of plants to UV-induced oxidative stress, delays senescence, promotes the growth of ageing seedlings, regulates the water status of plants under condition of drought Enzymatic: Glutathione peroxidase—Protection against haemoglobin oxidation. Nonenzymatic: Growth promoter
Zinc (Zn)	Zn ²⁺ , ZnSO ₄ °, ZnCl ⁺ , ZnHCO ₃ ⁺ , ZnCO ₃ °	Fertilizers, galvanizing, dyes, paints, timber treatment, mine tailings	Plant: formation of growth hormones (auxin), seed and grain formation, promotes maturity, protein synthesis and transformation, and consumption of carbohydrates Animal: Enzymatic: carbonic anhydrase— ${\rm CO_2}$ formation; regulation of acidity; carboxypeptidase—Protein metabolism; alcohol dehydrogenase—alcohol metabolism; cytocuprein—superoxide (${\rm O_2}^-$) dismutation Nonenzymatic: Eczema control in cattle

"heavy metals" or "heavy metalloids" and include both cationic and anionic forms. Both groups can be toxic to plants, animals, and humans above certain concentrations specific to each element and target biota.

Soil represents the major sink for minor elements released into the biosphere through both geogenic (i.e., weathering or pedogenic) and anthropogenic (i.e., human activities) processes. The mobility and bioavailability of minor elements in soils are affected by adsorption onto mineral surfaces, precipitation as salts, formation of stable complexes with organic compounds, and bioaccumulation and biotransformation by microorganisms (Adriano, 2001). Soil is a biologically active integral component of the terrestrial ecosystem in which higher plants, soil constituents, and soil organisms interact, where the available energy in the form of organic and inorganic compounds promotes microbial activity and microbial weathering processes.

Bioavailability, which refers to how much of an element is available to living biota including plants and soil microorganisms, defines the relationship between its concentration in the terrestrial environment and its level that actually enters the receptor causing either a positive or negative effect on the organism. Bioavailability is species-specific because the dose that reaches an organism's target organs or tissues resulting in a biological response varies among receptors (Stokes et al., 2005). Bioavailability often refers to the extent to which an element can desorb, dissolve, or otherwise dissociate from the solid phase in which it occurs to become accessible (i.e., bioaccessibility) for absorption (Alexander and Alexander, 2000).

Chemical bioavailability is now considered an important environmental consideration because availability may be mitigated once the element comes in contact with the soil or sediment. For this reason, both soil fertility status as well as risk assessment of contaminated sites require quantification of chemical bioavailability as is carried out for other nutrients in fertilizer recommendations and risk calculations (Hrudey et al., 1996). In both fertilizer recommendations and contaminated site assessment, bioavailability, which addresses the fundamental issue of exposure of a receptor (plant) to the element in question, is not dictated by the total element concentration in the soil, but rather by the fraction of the total amount that is biologically available. Consequently for the element to become available, it must be desorbed from the soil particle and transported to the root via the soil solution. The amount of an element in soil that is bioavailable depends on a variety of factors including the properties of both the element and the soil environment (Black, 2002; Adriano et al., 2004).

This chapter covers the following aspects of the essential micronutrients (Cu, Zn, Se, Mo, Fe, Mn, Co, Ni, B, and Cl) in relation to their bioavailability in soils: (1) sources and dynamics, (2) indicators and factors affecting bioavailability, and (3) bioavailability implications to soil testing.

11.5.2 Sources of Micronutrients

Just like the major elements such as P and K, micronutrients reach the soil environment through both pedogenic and anthropogenic processes (Tables 11.14 and 11.15). Most micronutrients

occur naturally in soil parent materials, chiefly in forms that are not readily bioavailable for plant uptake. Often the micronutrient concentrations released from the soil by natural pedogenic processes are largely related to the origin and nature of the parent material. On the other hand, micronutrients added through anthropogenic activities including fertilization typically have higher bioavailability (Naidu et al., 1996a). Fertilizer and manure additions to agricultural soils are the major sources supplying micronutrients for plant growth (Tables 11.15 and 11.16). Anthropogenic activities, associated with industrial processes, manufacturing and the disposal of domestic and industrial wastes, also contribute to micronutrient enrichment of soils (Adriano, 2001).

11.5.3 Dynamics of Micronutrients in Soils

Micronutrients undergo both chemical and biological transformations including retention, redox and methylation reactions while they are retained in the soil by sorption, precipitation, and complexation, and removed by plant uptake and leaching. Although most micronutrients are not subject to volatilization losses, Se tends to form gaseous compounds through redox and methylation reactions (Frankenberger and Karlson, 1995). When micronutrient solution concentration is low and sorption surfaces large, sorption/desorption processes will govern the soil solution concentration (Tiller, 1989) while the fate of micronutrients in the soil depends on both soil properties and environmental factors.

11.5.3.1 Chemical Transformation Processes

11.5.3.1.1 Sorption and Complexation

Chemical interactions that contribute to micronutrient retention by soil colloids include sorption and complexation with inorganic and organic ligands. Charged ions are attracted to charged soil surfaces by electrostatic and/or stronger covalent bonds (Mott, 1981), which can be specific or nonspecific in nature (Bolan et al., 1999). In nonspecific adsorption, the ion charge balances that on the soil surface by electrostatic attraction while in specific adsorption, chemical bonds form between the ions and the soil surface (Sposito, 1984). Metal ion binding on soil organic matter (SOM) is strongly pH dependent due to competition between metal ions and protons for the available binding sites and to the effect of pH on the electric charge development on SOM. Detailed descriptions of these processes are presented in Chapters 11 and 19 of *Handbook of Soil Sciences: Properties and Processes*.

11.5.3.1.2 Cation-Exchange Reactions

Although most soils have a net negative charge, this charge plays only a minor role in micronutrient reactions in soil. In general, for ions having the same charge, ions with the larger hydrated radius are selectively adsorbed. The many ion exchange selectivity coefficients reported in the literature have been determined in the presence of ligands but the effects of ion-pair formation and complex ions have been generally ignored. Comparisons between reported selectivity coefficients for various systems and exchange reactions can, therefore, not be made with confidence (Sposito, 1984). Very little information is available on the values of the coefficients for ion exchange between dominant and micronutrient cations in soil—water systems.

11.5.3.1.3 Specific Adsorption at Mineral Surfaces

Although most macronutrient cations are weakly retained by soils in exchangeable form, most micronutrient cations are strongly retained as inner sphere complexes with variable charged surfaces by the formation of covalent bonds. Although specific adsorption in the form of inner sphere complexes with variable charged mineral surfaces occurs most readily for metals that hydrolyze in water, such as most of the transition elements (Cu, Fe, Mn, Co, Zn, Ni) and some other divalent

TABLE 11.16 (continued) Micronutrient Content of Some Commonly Occurring Fertilizers Used in Agricultural Production

micronutrients, adsorption reactions usually involve the formation of an inner sphere complex between the hydroxo-metal ion and the deprotonated negatively charged surfaces of Al, Mn, and Fe oxides. The relative affinities of the metals tend to follow the *Irving-Williams* order:

$$Cu^{2+} > Zn^{2+} > Ni^{2+} \sim Co^{2+} > Fe^{2+} > Mn^{2+}$$

11.5.3.1.4 Adsorption by Soil Organic Matter

Metals can react with SOM by ion exchange, complexation, and precipitation. Although complexation as inner sphere complexes between the cation and SOM coordinating functional groups is thought to be the most important reaction, the difficulties involved in studying SOM preclude accurate separation of the processes in most experiments. The retention of metals by SOM at pH 5.8 decreases in the order (Schnitzer and Khan, 1978):

$$Fe = Al = Cr = Hg = Pb = Cu > Cd > Zn > Ni > Co > Mn$$

Although multiligand complexes can form with simple organic acids, 1:1 complexes occur mainly with ligands of the structurally complex macromolecules in SOM, but two or more donor atoms in the macromolecule may be involved in the complexation reaction. Because electron donors in SOM are mainly O, N, and S, the important binding groups are as follows: -COOH (carboxyl), -OH (enolic and phenolic), -SH (thiol), $-\text{NH}_2$ (amino), =O (carbonyl), and -S (thioether). With increasing pH, carboxyl, phenolic, alcoholic, and carbonyl functional groups dissociate, thereby increasing their affinity for cations. This results in SOM having a high affinity for micronutrients cations.

Micronutrients are known to form organic complexes that affect their sorption onto soil particles (Adriano, 2001; He et al., 2005). For example, Bolan et al. (2003a) demonstrated that the addition of organic manures increased the complexation of Cu in soils. Additionally, they observed that while Cu^{2+} adsorption measured as the change in the total Cu in

soil solution was not affected by biosolid addition, Cu complexation measured as the change in free Cu²⁺ concentration, increased with increasing level of biosolid.

Modeling of the binding of metals to humic materials as in MINTEQA2 is in its infancy with most work having been conducted on organic matter dissolved in surface waters rather than on SOM (Susetyo et al., 1991). More research is needed to develop suitable models that quantify metal retention by SOM.

The extent of micronutrients-organic complex formation, however, varies with a number of factors including temperature, steric factors, and concentration. All these interactions are controlled by solution pH and ionic strength, nature of the micronutrients species, dominant cation, and inorganic and organic ligands present in the soil solution.

11.5.3.1.5 Precipitation

At high pH and in the presence of SO₄²⁻, CO₃²⁻, OH⁻, and HPO₄²⁻, precipitation appears to be the predominant process when micronutrient cation concentrations are high (Naidu et al., 1996b). This occurs when the ionic product in the solution exceeds the solubility product of that phase. In normal soils, precipitation is not very important, but in heavy metal contaminated soils, the precipitation process can play a major role in remediation, especially under alkaline pH. Increasingly, addition of phosphate is being used to precipitate excessive levels of micronutrients such as Zn (He et al., 2005).

11.5.3.1.6 Leaching and Runoff

Micronutrients occur in solution either as free ions or soluble complexes that are prone to leaching. L'Herroux et al. (1997) showed that repeated applications of swine manure slurry increased the concentrations of Mn, Co, and Zn in drainage water manyfold. Similarly, Moore et al. (1998) found increased soluble Cu and Zn in runoff with increasing metal loading through poultry manure application, obtaining a strong relationship between dissolved organic carbon (DOC) and soluble Cu and Zn in the runoff.

However, pretreating the manure with $Al_2(SO_4)_3$ decreased runoff losses of these micronutrients as a result of sorption onto $Al(OH)_3$ formed upon hydrolysis of $Al_2(SO_4)_3$.

Migration of micronutrients in soils after manure slurry applications is greatly enhanced by DOC (Japenga et al., 1992; del Castilho et al., 1993; Li and Shuman, 1997; Hsu and Lo, 2000). Acidification due to nitrification from applied manures releases micronutrients from the solid phase (Japenga et al., 1992; del Castilho et al., 1993). Thus, while organic matter in manure byproducts may provide some buffer against metal bioavailability, it does not prevent the metal from being more mobile.

11.5.4 Biological Transformation Processes

11.5.4.1 Plant Uptake and Bioaccumulation

Micronutrients are applied to overcome deficiencies, thereby increasing crop production. When micronutrients in soil are deficient, yield responses to fertilizer and manure are often observed due to increased uptake. Typical examples of yield responses to micronutrients in several crops are presented by Mortvedt (1999). Although plant uptake is a major sink for micronutrients, only a small fraction of that applied to soil is ever taken up because the greatest proportion is immobilized.

Microorganisms can bioaccumulate micronutrients from substrates containing very low concentrations. Bacteria produce large quantities of extracellular polymers with anionic properties that remove soluble micronutrients ions from solution (Srinath et al., 2002) while many fungal products, such as glucans, mannans, melanins, chitins, and chitosans can act as efficient biosorption agents (Blackwell et al., 1995). Thus, microorganisms are competitors with plant roots for these nutrients.

11.5.4.2 Oxidation/Reduction

Redox reactions, both chemical and biological, affect the bioavailability of micronutrients such as Fe, Mn, and Se. In agricultural soils, the reduced forms of Fe²⁺ and Mn²⁺ are most available while Se is more available in the oxidized [Se(VI)] form. Because of the great heterogeneity in the pore space of most soils, zones of reducing and oxidizing conditions are often in close proximity to one another allowing roots to access the available forms at different points in the soil. Application of manures to soils that are subject to reducing conditions (very wet) can result in losses of micronutrients such as Mn by leaching (L'Herroux et al., 1997), while micronutrients such as Co sorbed on sesquioxides under oxic conditions (McLaren et al., 1984) can be released due to manure-induced reduction of these oxides. Temporary flooding of alfalfa fields often result in substantial yield decreases due to the induced Mn²⁺ toxicity from the reducing conditions.

11.5.4.3 Methylation/Demethylation

While some metals (As, Hg, and Se) can be methylated and lost by volatilization (Cernansky et al., 2009), none of the plantessential micronutrients are involved. Thus, this process is only of interest in metal contaminated sites.

11.5.5 Bioavailability of Micronutrients in Soils

11.5.5.1 Definition

The bioavailability of an element in the soil environment is defined as the fraction of the total that is present in the soil solution and on the solid phase that is available to the plant (Naidu et al., 2008). Considerable controversy exists as to "what constitutes the bioavailable fraction," including the definition itself and the methods used for its measurement. For instance, microbiologists often regard the bioavailable fraction as the concentration that can induce a change either in morphology or physiology of the organism, whereas plant scientists regard the plant-available pool as the bioavailable fraction, which is the definition that will be used here. Physical accessibility of micronutrients for uptake occurs either through movement of ions to roots by diffusion and mass flow or through root extension to the site of the nutrient. Chemical accessibility requires that nutrients remain in the soil solution in the form in which they are taken up (Marschner, 1995). Because the transformation of micronutrients in soils is a dynamic process, bioavailability changes with time.

11.5.5.2 Indicators of Bioavailability

Micronutrients occur in various fractions in soils that include the following (Shuman, 1991):

- 1. Structural components of primary and secondary minerals (e.g., Mn in manganous oxide)
- 2. Precipitated in inorganic forms, including those occluded by Fe, Al, and Mn oxides (e.g., Zn)
- 3. Complexed by organic matter (e.g., Cu)
- 4. Incorporated into organic matter including microbial biomass (e.g., B, Se)
- 5. Specifically adsorbed onto silicate clay minerals and Fe, Al, and Mn oxides (e.g., Zn)
- 6. On clay and organic exchange sites
- Water soluble as free and complexed inorganic and organic ions

Despite only small amounts of micronutrients being present in exchangeable (6) and water soluble fractions (7) from which uptake occurs, they are continuously replenished from other less-soluble fractions, ensuring continuity of supply. Micronutrient bioavailability in soils can be assessed using chemical and biological tests.

11.5.5.2.1 Chemical Tests

11.5.5.2.1.1 Single Extraction A range of chemical extractants including mineral acids (e.g., 1 M HCl), salt solutions (e.g., 0.1 M CaCl₂), buffer solutions (e.g., 1 M NH₄OAc), and chelating agents (e.g., DTPA) have been used to predict micronutrient bioavailability in soils (Sutton et al., 1984; Payne et al., 1988; Sims and Johnson, 1991) but chelating agents, such as EDTA and DTPA are usually more reliable (Sims and Johnson, 1991), since they are more effective in removing potentially bioavailable fractions. However, they do not actually measure availability (Beckett et al., 1983a, 1983b). For example, although the

DTPA-extractable Cu was linearly related to Cu application rate, no relation with corn grain or leaf tissue Cu existed (Payne et al., 1988). Nevertheless, because DTPA-extractable micronutrients increase with metal level in soil (Wallingford et al., 1975; Haleem et al., 1992; Martinez and Peu, 2000), which is related to crop uptake (Wallingford et al., 1975; Mullins et al., 1982; Bibak, 1994; Duffera et al., 1999), DTPA-extractable micronutrients and plant uptake may in some cases be fortuitously related (Beckett et al., 1983a, 1983b).

11.5.5.2.1.2 Sequential Fractionation Sequential fractionation schemes are often used to examine the redistribution or partitioning of micronutrients in various chemical forms that include soluble, adsorbed (exchangeable), precipitated, organic, and occluded. Although the extraction procedures vary between chemical fractionation schemes, generally the solubility and bioavailability of micronutrients in soils decrease with each successive step in the scheme (Basta and Gradwohl, 2000). Specific chemical pools measured by chemical fractionation have been correlated with plant uptake and have been successful in predicting micronutrient availability in soils (Shuman, 1991). Because chemical extraction is matrix dependent, validation for different micronutrients sources, such as inorganic fertilizer, and organic biosolid and manure by-products must be carried out.

The diversity of reagents used to extract specific metal forms from soils makes comparison of results difficult (Table 11.17). Even when the same reagent is employed, the efficiency of extraction depends on the nature of sample, its particle size distribution, duration of extraction, pH, temperature, strength of extractant, and solid:solution ratio (Miller et al., 1986). Because chemical reagents used for extraction may themselves alter the indigenous speciation of micronutrients, milder extractants are usually more selective albeit less efficient for specific fractions than more aggressive reagents, which may extract other forms as well (Lake et al., 1984; Ross, 1994).

Redistribution of micronutrients as measured by fractionation techniques depends on their source. While fertilizer-applied micronutrients tend to remain in soluble and exchangeable form, those applied in manure are in the organic-bound form. For example, after fractionation of metal-organic components in a manure-amended soil, del Castilho et al. (1993) found that strongly bound organic-metal complexes (Cu and Zn) were mostly associated with hydrophobic acids (phenols) and neutrals (hydrocarbons) while the weakly bound micronutrients were complexed with hydrophilic neutrals (i.e., carbohydrates).

11.5.5.2.1.3 Diffusive Gradient Thin Film Diffusive gradient thin film techniques physically mimic the removal of metals by a plant by having a layer of chelating resin behind a diffusive layer (usually a gel faced with a filter membrane) that is in contact with the soil solution. This chemically and physically well-defined system introduces a sink for ions in the soil, which results in a concentration gradient in the soil solution adjacent to the device and a consequent supply of ions from the solid phase into the locally depleted solution (Smith et al., 2007).

11.5.5.2.1.4 Isotopic Techniques Methods, such as isotopic dilution and the isotopic exchange kinetics (IEK) method have been shown to measure phytoavailable elements in soils (Hamon et al., 2008; Hedley, 2008). Isotopic dilution techniques consist of spiking soil with the metal before cropping after which the specific activity (isotope:nonisotope ratio) of the plant and soil solution are measured; from this, the amount taken up from the isotopically exchangeable pool can be calculated, allowing for a good estimation of the amount of phytoavailable element.

The IEK technique, which is used to study isotopic exchange as a function of time, can be employed in conjunction with other techniques to describe the transfer of Co (Wendling et al., 2009), Cu (Ma et al., 2006), Zn (Sinaj et al., 1999; Zhang et al., 2006), Ni (Echevarria et al., 1998), and Se (Goodson et al., 2003) in soils and is very useful in describing plant availability in terms of quantity/intensity (*Q/I*) concepts (Hamon et al., 2002).

The labile pool of an element in soil, whether determined by radioactive or stable isotopes, can be considered as a relatively unambiguous assessment of the chemical and biological reactivity of that metal in soil compared with fractions isolated by chemical extractants (Hedley, 2008). However, it should be recognized that isotopic exchange determinations are based on the assumption that the added spike (radioisotope or stable isotope) remains 100% available for exchange. Any fixation ("irreversible" sorption) of some of the spike by reactive soil phases will result in an overestimate of the size of the labile pool (Hamon et al., 2002).

11.5.5.2.2 Biological Tests

11.5.5.2.2.1 Phytoavailability Plant availability of micronutrients largely depends on the source, soil type, and plant species (Martinez and Peu, 2000). While the application of micronutrient fertilizers usually increases the uptake of the elements by plants, application of manure by-products can both increase or decrease micronutrient concentrations in plants. For example, addition of farmyard manure increased the uptake of soil Co and Mn by winter wheat (Bibak, 1994), while acidification of soils by manure increased the B and Zn concentrations in the soil solution and uptake by maize (Jahiruddin et al., 2001). On the other hand, three annual of applications of ~24 kg Cu ha⁻¹ as Cu-enriched swine manure increased Cu concentration in the corn ear leaf, but did not affect either corn grain yield or grain Cu concentration (Kornegay et al., 1976). Similarly, the uptake of Se from Se-enriched cattle manure was found to be less than that from an inorganic source (Ajwa et al., 1998) and the addition of cattle manure decreased the concentration of borate anions in soil solution and the subsequent plant uptake of B (Yermiyahu et al., 2001).

11.5.5.2.2.2 Microbial Availability Long-term applications of biosolids to agricultural land can reduce microbial activity in soils as a result of high concentrations of micronutrients (McGrath, 1994). In contrast, only limited studies have examined the direct effect of manure-borne micronutrients on microbial activity. Huysman et al. (1994) showed that in soils receiving

TABLE 11.17 Selected References on the Array of Reagents Used to Partition the Chemical Forms of Micronutrients Derived from Various Sources in Soils

					Fraction/Form				_
Source	Element	Soluble	Exchangeable	Adsorbed	Organic	Oxide	Carbonate	Residual	Reference

swine manure for 5 years, there was no effect of Cu on anaerobic bacteria or fungal activity, but aerobic Cu-resistant bacteria increased with increasing soil DTPA Cu concentration, indicating that this may provide a sensitive measure of Cu bioavailability in soils. Application of swine and cattle manure slurries to grasslands acidifies soil while increasing total C and N contents, resulting in significant decreases in microbial biomass C and N. This suggests a decrease in the microbial turnover rate of C and N in manure-amended soil, apparently caused by increased solubilization of Cu, Ni, and Zn (Christie and Beattie, 1989). Organic complexation of Cu and other metals in biosolids and manures may be the main reason for the lower level of toxicity to soil biota of this form compared to inorganic salts, indicating that both microbial and plant toxicity is largely controlled by the free metal ion concentration (van Rhee, 1975; Brookes and McGrath, 1984; McGrath, 1994).

11.5.6 Factors Affecting Bioavailability of Micronutrients in Soils

11.5.6.1 Soil Interactions

Properties of the soil and its ambient solution determine the dynamic equilibrium between micronutrients in solution and solid phases, thereby affecting their bioavailability. Micronutrients interact with particulates by metal ion adsorption at surface sites, ion exchange with clay minerals, binding with organic-coated particulate matter or organic colloidal material, and by adsorption of metal-ligand complexes. All of these interactions are controlled by application of various soil amendments, pH, ionic strength, nature of the metal species, dominant cation, and inorganic and organic ligands present in the soil solution.

11.5.6.1.1 pH

Soil pH has a marked effect on metal adsorption increasing from <20% to 100% within the narrow pH range of 3-5 for all metals except those that form oxyanions (Forbes et al., 1976; Kinniburgh and Jackson, 1981; Christensen, 1984; Brümmer et al., 1988; Tiller, 1989; Naidu et al., 1994). This pH range, called the adsorption edge, generally occurs 2-3 pH units below the value of the pK for the hydroxide solubility constant of the hydrated metal ion and is partly a function of the experimental conditions (Barrow, 1986). This pH effect on adsorption of micronutrients depends on initial solution concentration, nature of soil constituents, and metal retention capacity of soils. Increased adsorption of metal ions with increasing pH is due to both increased negative surface charge density (Naidu et al., 1994) and increased concentration of the MOH+ species in the soil system (Hodgson et al., 1964). As discussed above, at pH values less than the value of the point of zero net charge (pznc), an increase in soil pH leads to a marked increase in the negative electrostatic potential of a variable charge system, which promotes cation adsorption. However, the precise nature of this interaction between metal ions and particle surfaces is unclear as different mechanisms have been proposed to

explain the increasing metal adsorption with pH. For example, the rapid increase in adsorption of Zn within the adsorption edge was attributed to abrupt changes in the concentration of ZnOH $^+$ species as the pH increases toward the pK $_1$ of the hydrolysis of Zn $^{2+}$ (Barrow, 1986).

11.5.6.1.2 Ionic Strength

The effects of ionic strength on the adsorption of metals by soils are not as well understood as those of pH (Petruzzelli et al., 1985; Naidu et al., 1994). The effect of ionic strength on metal adsorption by soils depends on the surface properties of the particles being more pronounced in variable than permanent charge soils. Metal adsorption decreases with increasing ionic strength for permanent charge minerals (Garcia-Miragaya and Page, 1976; Schindler et al., 1987; Boekhold et al., 1993).

11.5.6.1.3 Index Cation and Solution Composition

Cation adsorption by soils is a competitive process in which the degree to which any cation is adsorbed depends on the concentrations and identity of the other cations present (Bolan et al., 1999). This phenomenon has practical implications on the behavior of micronutrients in soils because the concentration of several metal cations (e.g., Na⁺, Ca²⁺, and Mg²⁺) in soil solution ranges from <0.01 M in Oxisols to >0.1 M in saline sodic soils. Such changes in ionic strength and metal ion concentration can enhance the mobility and, thus, the bioavailability of micronutrients in soils, for example, by liming or gypsum application, both of which increase Ca²⁺ ions that can compete with micronutrients for adsorption sites.

11.5.6.1.4 Inorganic and Organic Ligands

Ligands play important roles in numerous soil chemical processes such as mineral weathering, control of dissolved micronutrient concentrations, and dissolution and plant availability of micronutrients (see Harter and Naidu, 1995). The soil solution also contains inorganic ligand ions such as Cl⁻, SO₄²⁻, PO₄³⁻, and NO₃⁻ whose concentrations vary considerably with soil type from >0.1 M in saline to <0.001 M in highly weathered soils. Such variations in ligand ion concentrations modify both the nature and surface interactions of the metal species present, leading to marked variability in metal bioavailability.

Dissolved organic material consists of a range of low molecular weight compounds including water soluble humic and fulvic acids, which are dominant except in the rhizosphere where simple organic compounds may dominate. Despite extensive studies of metal ions with organic matter (Stevenson, 1991), the values of the reaction constants need to be improved because only limited efforts have been directed toward understanding the role of low molecular weight organic acids in the dynamics of metals in the soil solution; this is due partly to the commonly held, but incorrect, belief that such organic material is rapidly degraded, and therefore short-lived, and partly to difficulty assaying the low concentrations of organic acids present. In the vicinity of plant roots, dissolved organic matter concentrations, often reaching millimolar levels, are high due to root exudates and microbial activity (Harter and Naidu, 1995), greatly enhancing the bioavailability and uptake of soil P, Cu, Fe,

Mn, and Zn (Braum and Helmke, 1995). The role of plant and microbial exudates on metal reactions in soils is an area that lacks information and is an active area of research.

11.5.6.2 Soil Amendments

A number of amendments can change micronutrient bioavailability either through mobilization that releases the micronutrient into soil solution for plant uptake or through immobilization where the micronutrient concerned is removed from soil solution either by adsorption, complexation, and precipitation, rendering the micronutrient unavailable for plant uptake and leaching to groundwater.

11.5.6.2.1 Chelating and Complexing Agents

When a micronutrient ion combines with an electron donor containing two or more donor groups, a complex or coordination compound with one or more rings called a micronutrient chelate is formed. A "chelate" (Greek, chela meaning claw) is so named because these species can coordinate at several or all positions literally wrapping themselves around a central micronutrient ion. Chelating agents, which have a high affinity for micronutrients ions such as Fe, Cu, and Zn, can be used to enhance the solubilization of micronutrients by the formation of soluble micronutrients chelates such as EDTA, EDHA, DTPA, and EHPG (Table 11.16). The effectiveness of a chelate in mobilizing soil micronutrients depends on several factors, including species, micronutrient:chelate ratio, thermodynamic stability constants, presence of competing cations, soil pH, stability of the micronutrient-chelate complex, the ageing, and the extent of micronutrient on soil constituents (Grčman et al., 2001). Synthetic chelates appear to mobilize micronutrients from the exchangeable, organic, and carbonate-bound fractions, but not from the oxide fraction (Elliott and Shastri, 1999). The use of chelating agents may induce the solubilization of other than the target micronutrients, which may become phytotoxic (e.g., Al and Mn).

11.5.6.2.2 Phosphate Compounds

Phosphate compounds can enhance the immobilization of micronutrients in soils by various processes including direct adsorption by P compounds, phosphate anion-induced adsorption, and precipitation with solution P as phosphates (Bolan et al., 2003b). Because the phosphate anion is very effective in desorbing certain oxyanions, such as selenite and molybdate, it is often used as an extractant to measure the amount of adsorbed oxyanions (James et al., 1995; Aide and Cummings, 1997). Phosphate also competes strongly with molybdate (MoO_4^{2-}) for adsorption sites, thereby resulting in increased desorption of the latter (Barrow, 1973; Xie et al., 1993).

Interaction of P with micronutrients also occurs within the plant. For example, increasing levels of P can induce or accentuate symptoms of Zn deficiency in plants grown in soils or culture media low in available Zn (Loneragan et al., 1979; Cakmak and Marschner, 1987). This disorder is commonly known as "P-induced Zn deficiency," which is the most widely examined P-trace element interaction in soil–plant systems (Loneragan and Webb, 1993). Five plausible mechanisms involving P, which may operate separately

or concurrently, can cause decreases in Zn concentrations in the plant, depending upon plant species and environmental conditions (Loneragan et al., 1979; Loneragan and Webb, 1993): (1) dilution of tissue Zn by growth promoted by P addition, (2) inhibition of Zn uptake by roots as a result of competition with the cations accompanying the P, (3) increased P-induced Zn adsorption by Fe and Al oxide-rich variable charge soils, (4) greater Zn requirement in shoots induced by P additions, and (5) inactivation of Zn within the shoot in the presence of high P levels (Loneragan and Webb, 1993).

11.5.6.2.3 Liming Materials

Although liming is primarily aimed at ameliorating soil acidity, bioavailability of Zn, Mn, Cu, and other cationic micronutrients can be reduced as a result of decreased mobility by increased sorption/precipitation and competition between Ca²⁺ and micronutrients ions on the root surface for uptake (Brown et al., 2009). Because liming also increases Mo (molybdate) mobility in soils by decreased sorption on soil surfaces, Mo in soil solution available for uptake is increased.

11.5.6.2.4 Organic Composts

The most important organic fertilizers are biosolids and animal manures. Unlike biosolid application, regulations governing livestock and poultry manure are generally based on total N and P loading so that excessive amounts of some micronutrients are inadvertently applied (Cu and Zn in swine and As in poultry manure) (Bolan et al., 2004), requiring pretreatment to reduce bioavailability. For example, treatment of poultry manure with alum $[Al_2(SO_4)_3]$ decreases the concentrations of water-soluble Zn and Cu. Organic amendments increase the CEC of soils, thereby resulting in increased micronutrients adsorption.

Micronutrients form both soluble and insoluble complexes with organic materials, a process that depends on the nature of the organic matter (Bolan et al., 2003a). With increasing pH, carboxyl, phenolic, alcoholic, and carbonyl functional groups on SOM dissociate, thereby increasing the affinity of ligand ions for micronutrient cations. For example, addition of manure increases the adsorption and complexation of Cu by the soil with DOC being primarily responsible (Bolan et al., 2003a).

11.5.7 Bioavailability Implications for Soil Testing and Risk Assessment

11.5.7.1 Soil Testing and Crop Response

While most soil testing focuses on the bioavailable fraction of micronutrients for fertilizer recommendation purposes, most risk assessment models assume that the target element is 100% available, which is clearly not the case; consequently, a number of soil tests have been developed to predict micronutrient availability. Descriptions of micronutrient deficiency symptoms and the soil conditions in which deficiencies are likely to occur are presented in Table 11.18 while selected references on crop responses to micronutrients are presented in Table 11.19. In this section, we focus on Zn, Mn, Cu, Fe, B, Cl, Mo, and Ni that are essential for crop growth, development, and yield.

TABLE 11.18 Deficiency Symptoms and Crop Response to Micronutrients

Micronutrient	Deficiency Symptoms	Crop Response
Boron	B deficiencies symptoms vary with plant species including impaired meristem activity (dieback of young growth, malformed leaves often manifest as "witches broom"), impaired cell wall development (cracking of stem and petioles), and poor pollen tube development (reduced seed set, fruit fall, and deformed fruit)	B deficiency occurs on a wide range of soils (coarse-textured, highly weathered, shallow, volcanic ash, and thin soils over calcareous material) and crops
Cobalt	Co is essential for N fixation in plants Deficiency causes ill-health in ruminants. Co deficiency is associated with vitamin B12 decreases in animals	Co deficiency occurs in acidic and highly leached soils, soils derived from granites, calcareous, and peat soils Co is usually administered directly to animals
Copper	Catalyst for several enzymes Deficiency effects new growth with wilting, withering of youngest growth Cu deficiency in grain crops is known as reclamation disease, wither-tip, yellow-tip, or blind ear. In woody plants, such as	Cu deficiency occurs in: peat and muck soil; alkaline and calcareous soils, especially sandy soils or those with high levels of free $CaCO_3$: highly leached soils; or soils heavily fertilized with N, P, and Zn fertilizers Cu deficiency is corrected mostly by soil application rather than
Iron	citrus, this is known as dieback or exanthema A major element for chlorophyll production. Deficiency turns new leaves pale yellow or white while the veins remain green Difficult for plants to absorb and moves slowly within the plant. High soil pH prevents plants absorption of Fe	foliar application; Cu is also applied as a fungicide spray Fe deficiency is caused by imbalance of metallic ions (Cu and Mn), excessive P, a combination of high soil pH, high lime application, high soil moisture, cool temperature, and high levels of bicarbonate in the rooting medium Fe deficiency can be corrected by direct application of Fe fertilizer to soils or as foliar application
Manganese	Works with plant enzymes to reduce nitrates before producing proteins Mn deficiency turns young leaves a mottled yellow or brown Mn deficiency is called gray speck in oats, yellow disease in spinach, speckled yellow in sugar beets, marsh spot in peas, crinkle leaf in cotton, stem streak necrosis in potato, streak disease in sugarcane, mouse ear in pecan, and internal bark necrosis in apple	Mn deficiency occurs in: shallow peaty soils overlying calcareous subsoils; alluvial soils and marsh soils derived from calcareous parent materials; poorly drained calcareous soils with high organic matter; acid sandy mineral soils that are low in native Mn or high lime application Mn deficiency is corrected by soil application of Mn fertilizers or by foliar application
Molybdenum	Mo is an essential constituent of enzyme necessary for N ₂ fixation. Deficiency causes leaves to turn pale, with scorched-looking edges, and irregular growth. Mo deficiency is known as whiptail disease in brassica plants and yellow spot disease in citrus. Mo deficiency is frequently associated with legume crops as Mo is an essential constituent of N ₂ fixation	Mo deficiency occurs in acid sandy soils, highly podsolized soils, highly weathered tropical soils and well drained sandy soils Mo deficiency can be corrected by soil application, foliar spray, and seed treatment with Mo; lime application can overcome Mo deficiency
Nickel	A constituent of four enzymes: urease, methyl coenzyme M reductase, hydrogenase, and carbon monoxide dehydrogenase Without Ni, toxic levels of urea accumulate, leading to the formation of necrotic lesions. In tomato, chlorosis in the youngest leaf leading to necrosis of their meristematic tissues; in cereals (wheat, oats, and barley) growth depression, premature senescence and decreased Fe levels	Occurs mainly in woody perennials such as pecan and coffee. Can be induced as a result of complexation by glyphosate. Foliar sprays are effective in overcoming deficiency
Selenium	Essential for higher animals; Se deficiency causes muscular dystrophy or white muscle disease	Se deficiency occurs in strongly leached soils
Zinc	Zinc is required in a number of enzymes and plays an essential role in DNA transcription Deficiency produces stunting, yellowing, and curling of small leaves A typical symptom of deficiency is the stunted growth of leaves, commonly called "little leaf" and is caused by the oxidative degradation of the growth hormone auxin	Zn deficiency is caused by: low Zn content in soils, high lime application, or unavailability of Zn to the plant, and metabolic disorder within plants (e.g., imbalance between Zn and P) Zn deficiency can be overcome by soil and foliar application and avoiding imbalance between Zn and P

11.5.7.1.1 Diagnosis and Prognosis of Micronutrient Deficiencies or Toxicities

Dry matter and grain yield of a crop are determined by the ability of the roots of plants to extract micronutrients from the soil at rates that are nonlimiting for crop growth. Therefore, the amount of nutrient taken up by a crop is a measure of

availability. Analysis of selected plant parts (e.g., leaves, young growth), or whole shoots (Smith, 1980), is used as a diagnostic tool to identify micronutrients that may be limiting growth in contrast to soil tests that estimate the available pool. Plant analysis as a diagnostic tool is discussed in detail in Chapter 13.

TABLE 11.19 Selected References for Crop Responses to Micronutrients

Micronutrient	Crop Species	Application Rate	Observations	Reference
Cu	Barley (Hordeum vulgare L.) and wheat (Triticum aestivum L.)	50 kg Cu ha ⁻¹	Application levels about 4–5 times the usual for crop application. However, no detrimental effects in yield reduction or phytotoxicity in wheat. For barley, 50 kg Cu ha ⁻¹ decreased yield by 12% in the first year. The Cu levels in plants were <9 mg kg ⁻¹	Gupta and Kalra (2006)
	Wheat	6.7-13.4 kg Cu ha ⁻¹	Application of Cu increased grain yield	Rehm (2008)
	Wheat and barley	0.7–2.1 kg Cu ha ⁻¹	Application of Cu increased grain yield and concentrations of wheat and barley grown on neutral to acidic soils	Gartrell and Glencross (1968)
Zn	Barley and wheat	50 kg Zn ha ⁻¹	Zn applications of 50kg ha^{-1} for 2 years resulted in crop tissue Zn levels as high as 105mg kg^{-1} did not cause any phytotoxicity in cereals	Gupta and Kalra (2006)
	Rice	13.5 kg Zn ha ⁻¹	Zn at 13.5 kg ha ⁻¹ , increased dry matter, tissue Zn concentration and grain yield	Slaton et al. (2005)
	Wheat and barley	0.7–2.1 kg Zn ha ⁻¹	Application of Zn increased grain yield of wheat and barley grown on neutral to acidic soils	Gartrell and Glencross (1968)
Fe	Soybean and Pigeon pea	20 kg Fe ha ⁻¹	Application of Fe at 20 kg Fe ha ⁻¹ increased grain yield of soybean and pigeon pea by 9% and 414%, respectively	Hodgson et al. (1992)
	Soybean	$400\mathrm{g}$ Fe EDTA (5.5% Fe and 2% EDTA) ha $^{-1}$	The Fe application with 80 kg N ha ⁻¹ gave the highest seed yield	Caliskan et al. (2008)
Co	Faba bean (Vicia faba L.)	$20mgL^{-1}$ Co as foliar spray	Co application at $20mgL^{-1}$ increased grain yield by 218% and total protein by 48%	Hala (2007)
Mn	Lupinus angustifolius L.	1.7 kg Mn ha ⁻¹ in 200 L foliar application	Foliar Mn prevented deficiency, and increased grain yield	Hannam et al. (1984)
	L. angustifolius L.	3.5–15 kg Mn ha ⁻¹	Soil application increased grain yield, decrease amount of split seed at maturity	Brennan (1999)
Ni	Tomato	$30\mathrm{mg}\mathrm{Ni}\mathrm{kg}^{-1}\mathrm{soil}$	This level, increased quality of fruit and auxin and gibberlin contents	Gad et al. (2007)
	Pecan (<i>Carya illinoinensis</i> [Wangenh.] K. Koch)	$10-100mg~L^{-1}$ (plus urea and surfactant)	Decreased "water-stage fruit-split" symptom of pecan reducing crop losses	Wells and Wood (2008); Malavolta and Moraes (2007)
Mo	Tobacco	1.1 kg Mo ha ⁻¹	This level of Mo and lime at 7.3 or $14.6\mathrm{t}$ ha ⁻¹ increased yield by 16% – 22%	Khan et al. (1994)
Se	Wheat	20 g Se ha ⁻¹	Se fertilization at 20 g ha ⁻¹ increased grain Se content by four- to sevenfold	Stroud et al. (2010)

11.5.7.1.2 Soil Analysis to Assess Available Micronutrient Pool

The objectives of a micronutrient soil test are to (1) group soils into classes for fertilizer recommendations, (2) predict the probability of a response to an application, and (3) evaluate soil productivity (Fitts and Nelson, 1956). A good soil test should (1) extract all or a proportionate fraction of the available form or forms of a nutrient, (2) accurately and in a timely manner measure the amount of the nutrient extracted, and (3) be correlated with the growth and response of each crop to each micronutrient under various conditions (Sims and Johnson, 1991). A detailed discussion of soil testing is presented in Chapter 13.

11.5.7.1.2.1 Zinc Zinc deficiency is widespread throughout the world, probably the most common micronutrient deficiency across a range of crop species (Takkar and Walker, 1993).

Usually, Zn deficiency in plants occurs in calcareous (high pH) soils because of low Zn availability or in coarse-textured (sandy), highly leached, acid soils because of their low total Zn content. Antagonisms between Zn and several other essential elements (e.g., P, N, and Cu) can also lead to Zn deficiencies (Loneragan and Webb, 1993). Recommended amounts of Zn fertilizer range from about 1 to 15 kg Zn ha⁻¹. Some crops particularly sensitive to inadequate soil Zn are corn, soybean, rice (*Oryza sativa*), field bean (*Vicia faba*), and citrus (*Citrus spp.*).

The sources of Zn used as fertilizers are presented in Table 11.16 with zinc sulfate crystal or granular form being the most common (Mortvedt and Gilkes, 1993). Zinc oxide has low effectiveness in the granular form as it is insoluble in water (Mortvedt, 1991). Because water solubility of the Zn source is important, at least 50% water solubility is required to be effective on calcareous soils (Gangloff et al., 2002; Westfall et al., 2002). However,

in acid soils, a wide range of products, including the oxide and sulfate, are equally effective as fine powders mixed thoroughly with the soil (Mortvedt and Gilkes, 1993).

11.5.7.1.2.2 Copper Usually, Cu deficiency occurs on highly leached, acid soils (low total Cu content), on coarse-textured (sandy) soils, and soils rich in organic matter. Recommended amounts of Cu fertilizer range from about 1 to 25 kg Cu ha⁻¹. Because amounts of Cu in excess of crop requirements are often applied particularly in manures and fungicides, Cu has a long residual effect in the soil and remains bioavailable for some considerable time after application; consequently, frequent applications are not required (Gartrell, 1981; Brennan, 2006).

Although soil applications are the commonest method used to correct Cu deficiency (Gartrell, 1981; Martens and Westermann, 1991), foliar sprays are effective in citrus, wheat, corn, and soybean (Martens and Westermann, 1991). Because some fungicides usually supply more Cu than is required by the crop, repeated applications can result in soil accumulation (Graham and Webb, 1991). Inorganic sources applied to the soil such as, Cu oxide, sulfate, carbonate, nitrate, and chloride are effective in correcting deficiencies in crops (Gartrell, 1981).

Bioavailability of Cu fertilizers is affected by (1) the method of placement, (2) ability of the Cu product to produce Cu⁺² ions in the soil or rhizosphere, (3) reactions of Cu with soil, and (4) different requirements of plant species due to differences in growth rate, efficiency of absorption, or translocation in the plant. Because Cu is immobile in the soil, its availability is greatly influenced by the number of granules per unit volume of soil and the position in which they are placed. Banding Cu is more effective than topdressing, without incorporation into the soil. Copper fertilizer is ineffective in soil profiles that contain few absorbing roots, for example, dry soil. Applied at the same rate, large granules (fewer granules per unit volume) are much less effective than fine material (Gartrell, 1981).

11.5.7.1.2.3 Manganese Usually, Mn deficiency is associated with well-drained neutral to alkaline soils, and those rich in organic matter. In addition, because of their low total Mn content, highly leached, coarse-textured (sandy) acid soils are also frequently deficient for some crop species. Recommended amounts of Mn fertilizer range from about 2 to 20 kg Mn ha⁻¹. Manganese has a short residual effect in most neutral to alkaline soils, because the bioavailable Mn⁺² is rapidly oxidized to MnO₂. On the other hand, for sweet lupin (Lupinus angustifolius L) grown on acid sandy soils, the effect of 7.5 kg Mn ha-1 has lasted for some considerable time after application, while that of 50 kg Mn ha⁻¹ persisted for about 17 years (Brennan et al., 2001). Foliar application is the most efficient and effective method of correcting Mn deficiency in various crops grown on a range of deficient soils. Manganese deficiency is frequently encountered in cereals, cotton, peanuts, soybeans, and a range of fruits and vegetables (Martens and Westermann, 1991).

Band placement of manganese sulfate fertilizer is more effective than broadcasting at the same rate for soybean (*Glycine max*) (Mascagni and Cox, 1985) and sweet lupin (Brennan, 1999)

because concentration in the band reduces the rate of oxidation of Mn+2 to less available forms. Foliar sprays and band application of Mn sulfate were equally effective for soybeans (Mascagni and Cox, 1985). Soil moisture affects Mn availability with the seed-applied Mn being effective under adequate soil moisture but not drought conditions in soybean (Alley et al., 1978). For some crops (peanut [*Arachis hypogaea*], soybean, and wheat) and conditions, multiple rather than single foliar sprays are required (Cox, 1968; Hallock, 1979; Nayyar et al., 1985). The timing of the foliar spray in relation to crop development stage is also important for soybean (Gettier et al., 1984), corn (Mascagni and Cox, 1984), and sweet lupin (Brennan et al., 2008).

11.5.7.1.2.4 Iron Usually, Fe deficiency is a common problem in numerous crop species grown on alkaline soils containing free CaCO₃ in the soil profile (Marschner, 1995). In many cases, the problem stems from various factors that inhibit Fe absorption by plant roots or impair its utilization in metabolic process in Fe-inefficient species. Although rare, acid soils with deficient levels of Fe do occur, for example, in Florida and other similar areas (Welch et al., 1991). Recommended amounts of Fe fertilizer range from about 20 to 100 kg Fe ha-1 (Martens and Westermann, 1991). Iron has a short residual effect in most alkaline soils, because Fe⁺² is rapidly converted to unavailable forms. Foliar application is more effective at correcting Fe deficiency in various crops grown on a range of deficient soils. Iron deficiency is frequently encountered in a range of Fe-sensitive crops and/or Fe-inefficient cultivars (Welch et al., 1991). Growing Fe-tolerant species or varieties is an effective method for controlling Fe deficiency in crops grown on soils where Fe availability is low (Chen and Barak, 1982).

Because soil-fertilizer contact is limited in band placement, iron sulfate fertilizer banded in the soil is more effective than broadcasting at equal rates. However, Fe sulfate is frequently broadcast on pastures (Trifolium subterannean L.) where Fe deficiency has been induced by overliming acid soil (Brennan and Highman, 2001). Several other methods such as (1) mixing of Fe sulfate and sulfuric acid (Wallace, 1988; Martens and Westermann, 1991), (2) inclusion of organic residues with Fe sulfate (Mostaghimi and Matocha, 1988), and (3) inclusion of K₂SO₄ with Fe sulfate that corrected Fe deficiency in peanuts (Shaviv and Hagin, 1987) have been used to reduce the conversion of applied Fe to unavailable forms. Foliar sprays of inorganic (e.g., Fe sulfate) and organic Fe sources (e.g., Fe chelates) are very effective in correcting Fe deficiency (Martens and Westermann, 1991). Foliar applications of Fe sulfate are more effective than soil application of Fe chelate (FeEDDHA). Iron is less available in well-aerated soils due to insolubility of Fe(III) oxides; but availability can be promoted by increasing soil moisture that produces loci where some reduction of Fe(III) to Fe2+ can take place (Bjerre and Schierup, 1985). However, excessive soil moisture in calcareous soils may intensify Fe deficiency mainly due to the buildup of HCO₃ in the soil solution (Moraghan and Mascagni, 1991). Plant residues, manures, biosolids, charcoal, coal, and a range of by-products from manufacturing (e.g., polyflavoids and lignosulfonates) have been effective in alleviating Fe deficiency (Chen and Barak, 1982).

11.5.7.1.2.5 Boron Boron is an essential micronutrient where the range between deficiency and toxicity is smaller than for most other micronutrients. Plants respond to the activity of B in solution rather than to adsorbed B making the rate of desorption, which follows a first-order rate equation, important in B supply to the root. The bioavailability of B is determined by pH, texture, moisture, temperature, SOM, and clay mineralogy (Goldberg, 1997) while the adsorbing surfaces of importance are sesquioxides, clay minerals, lime, and organic matter. Boron adsorption increases initially with pH on both mineral and organic surfaces up to pH 8-10 and then decreases. Consequently, overliming acid soils can cause a temporary deficiency due to higher adsorption at high pH (Reisenauer et al., 1973). The roles of B in the plant include sugar transport, cell wall synthesis and structure, pollen tube growth, pollen viability, carbohydrate synthesis, respiration, and membrane integrity while excess B can cause impairment in a range of cellular functions, such as phenol and ascorbate metabolism, free radical generation, and detoxification (Cakmak and Romheld, 1997); but its primary role is still unknown. These changes may be direct or indirect functions of B deficiency.

Boron deficiency occurs on a wide range of soils (coarse-textured, highly weathered, shallow, volcanic ash, and shallow soils over calcareous material) and crops (alfalfa [Medicago sativa], beets [Beta vulgaris], peanut [A. hypogaea], brassicas [Brassica spp.], coffee [Coffea spp.], oil palm [Elaeis guineensis], cotton [Gossypium spp.], sunflower [Helianthus annuus], apple [Malus domestica], and grape [Vitis vinifera]) (Shorrocks, 1997) as well as many vegetable crops.

Deficiency symptoms vary with plant species including impaired meristem activity (dieback of young growth, malformed leaves often manifest as "witches broom"), impaired cell wall development (cracking of stem and petioles), and poor pollen tube development (reduced seed set, fruit fall, and deformed fruit). The main B sources used to correct B deficiency are borax (NaB₄O₇·10H₂O [11% B], NaB₄O₇ [21.4% B]), boric acid (B(OH)₃ [17.5% B]), and a range of crushed ores containing variable amount of B (Shorrocks, 1997). Boric acid and Solubor® (17.5% B), products readily soluble in cold water, are used as foliar applications. For annual crops, 1–2 kg B ha⁻¹ is the recommended rate (Shorrocks, 1997).

Boron toxicity commonly occurs in arid and semiarid environments on alkaline and saline soils (Nable et al., 1997). Continued application of irrigation water with high levels of B can lead to toxicity. The typical symptoms of B toxicity are leaf burn, chlorotic, and necrotic patches often on the margins and tips of older leaves (Bennett, 1993).

11.5.7.1.2.6 Chloride Chloride (Cl⁻) is essential for many plant functions such as a chemical balancing agent for K⁺ during the opening and closing of stomata, photosynthesis, cation balance and transport within the plant, counteracting the effects of fungal infection, and competing with NO₃⁻, thus promoting

the uptake of $\mathrm{NH_4}$ -N (Boyer et al., 1954; Fixen, 1993; Talbott and Zeiger, 1996). Deficiency symptoms vary with plant species including wilting and leaf chlorosis while toxicity manifests itself as leaf margin scorching, leaf drop in excessive situations, and leaf area reduction and thickening, resulting in reduced growth.

Because Cl $^-$ is highly soluble in water, leaching losses occur, where rainfall is high and soil drainage is good. If Cl $^-$ containing fertilizers (e.g., muriate of potash [KCl]) are not regularly used, Cl $^-$ deficiency can occur. In coastal regions with rough surf, atmospheric deposition of Cl $^-$ can be high, decreasing with distance from the coast. Chloride competes with other anions (e.g., NO $_3$ $^-$, SO $_4$ 2 $^-$) although little data are available on the specific interactions and competition between each anion.

11.5.7.1.2.7 Nickel Recently Ni, which has been shown to be an essential element for plants, is required in miniscule amounts as a piconutrient. It plays a vital part in the translocation of N in ureide-transporting woody perennials such as pecans (Carya illinoensis) and coffee (Coffea arabica) where a deficiency of Ni disrupts ureide, amino, and organic acid metabolism but its physiological role is poorly understood (Bai et al., 2006). In addition, it confers disease resistant on plants although much work needs to be done in this field (Wood and Reilly, 2007). Nickel appears to play a key role in the production of secondary plant metabolites that influence resistance to disease. Most soils contain adequate amounts of Ni but under certain specific conditions, for example, where glyphosate that strongly complexes Ni has been used as a herbicide, deficiencies can be induced (Yamada, 2010). Consequently, deficiency symptoms manifest themselves as those of N. Research in this field is still in its infancy.

11.5.7.1.2.8 Molybdenum Because Mo occurs in the soil solution as MoO₄²⁻, it interacts with other anions, particularly phosphate and SO₄²⁻ to reduce Mo uptake. In addition, it is strongly sorbed on sesquioxide surfaces at pH values below 7, decreasing 100-fold for each unit drop in pH. Thus, Mo deficiencies are mainly found on acid soils where bioavailability is low (Gupta, 1997). Consequently, liming acid soils can often supply sufficient Mo to meet the needs of many crops including legumes, which are most sensitive to deficiency. In legumes, because Mo is required by the Rhizobia in the fixation of N, deficiency of Mo is manifest as those of N. In addition, it is an activator for the nitrate reductase enzyme, crucial to the N nutrition of crops. Where Mo deficiency occurs, correction can be achieved by relatively small applications (~100 g Mo ha⁻¹) as foliar sprays in the form of sodium or ammonium molybdate.

12.1 Introduction

About 26% of the global ice-free land surface is occupied by soils with pH_w (pH determined in water) values of 6.5 or less, of which two-thirds have potential Al toxicity problems. Subsoil Al problems are estimated to encompass 16% of the ice-free land surface (Eswaran et al., 1997). Naturally, acid soils are found in regions where rainfall exceeds evapotranspiration (Jenny, 1941); H⁺ and eventually Al⁺³ replace basic cations lost from exchange sites through excess water transport. Most of the acid soils belong to the Alfisols, Histosols, Oxisols, Spodosols, and Ultisols orders of the U.S. Soil Taxonomy (Buol et al., 1997).

Agricultural and industrial processes also contribute to soil acidification. The conversion of ammonium to nitrate produces H⁺, which can require up to 3.6 kg CaCO₃ to neutralize the acidity produced by each kg of N (Adams, 1984). Plants excrete H⁺ from roots when cation uptake exceeds that of anions (Tang and Rengel, 2003). Legumes have excess cation uptake when most of their N is supplied via atmospheric fixation. Neutralization of acidity produced by N-fixing legumes can correspond to 54–550 kg CaCO₃ ha⁻¹ year⁻¹ (Bolan et al., 1991; Coventry and Slattery, 1991). Major sources of acid precipitation are atmospheric emissions of nitrogen and sulfur compounds from burning processes and their eventual transformation into nitric and sulfuric acids (Alewell, 2003).

12.2 Nature of Soil Acidity

Soils with pH_w values <5.5 have appreciable amounts of exchangeable Al^{3+} . The proportion of cation exchange sites occupied with Al^{3+} and the concentration of Al in the soil solution

increase with declining soil pH. In mineral soils, the soil solution Al concentration and the %Al saturation of the cation exchange capacity (CEC) approach zero between pH values of 5.5 and 5.8 (Kamprath, 1984; Sumner and Yamada, 2002). Organic soils have significant quantities of both exchangeable Al^{3+} and H^+ . Aluminum binds to organic matter in nonexchangeable forms, such that soil solution Al concentrations in organic soils are less than in mineral soils at the same pH value (Evans and Kamprath, 1970). At pH $_{\rm w}$ 5, organic soils have very little Al in the soil solution and Ca concentrations are high enough to overcome H^+ competitive effects on Ca uptake. Hydrolysis of the Al^{3+} in the equilibrium soil solution impacts the soil solution H^+ concentration and pH (Thomas and Hargrove, 1984).

Exchangeable acidity is extracted from soils with neutral unbuffered salt solutions such as KCl, to minimize changes in soil pH (Thomas and Hargrove, 1984). Soils also contain acidity, which is not extracted with neutral unbuffered salt solutions but is titrated with base. This nonexchangeable acidity represents the acid buffering capacity of soils, and includes Al bound to organic matter, H* associated with carboxyl groups of organic matter, hydroxy Al, and hydrated oxides of Fe and Al (Kamprath, 1978).

12.3 Acid Soil Constraints to Plant Growth

Plant growth in acid soils can be limited by a combination of toxicities (H+, Al3+, and Mn2+) and nutrient deficiencies (namely Ca, Mg, Mo, and P) (Kamprath, 1984; Sumner and Yamada, 2002). Responses to lime can involve amelioration of a combination of factors, wherein experiments in hydroponics often provide insight into the magnitude of individual constraints.

12.3.1 Hydrogen Toxicity

Visual root symptoms of excess H^+ usually occur at pH < 4.6 and entail stunted growth, brownish color, and little lateral root development. At low pH and low Ca^{2+} concentrations, root membranes are damaged, leading to loss of organic substrates and absorbed cations. Root injury due to H^+ can reduce the uptake of Ca, Mg, and K (Islam et al., 1980; Foy, 1984). Increasing solution Ca^{2+} concentration alleviates root injury due to H^+ (Lund, 1970; Moore, 1974; Runge and Rode, 1991; Sanzonowicz et al., 1998). Low pH has detrimental effects on rhizobium survival, legume host plant root infection, and nodule initiation (Andrew, 1978).

12.3.2 Aluminum Toxicity

Aluminum toxicity is a major constraint to plant growth in acid soils. The immediate and visible evidence of Al toxicity is a reduction in root length, which limits plant access to water and nutrients. Aluminum interferes with various root growth processes, namely, disruption of regulatory signals in root cap cells (Bennet and Breen, 1991), interference with cell division, enzyme activities, DNA replication, and P availability at membranes (Foy, 1984; Silva et al., 2002).

Concentrations of soil solution Al³⁺ that reduce crop growth are in the micromolar range (Kamprath, 1984). Soil solution Al³⁺ concentrations are related to the percentage of Al³⁺ saturation of the soil cation exchange sites, with a marked increase in solution concentration when Al³⁺ saturation exceeds 50% (Kamprath, 1978; Kamprath and Smyth, 2005). Determination of Al³⁺ and other cations in soil solutions is tedious and time consuming. It is simpler to measure exchangeable cations and diagnose Al³⁺ toxicity based on the %Al saturation of the cation exchange sites (Kamprath, 1970, 1978). A realistic measure of the soil cation exchange at a given pH value, the effective cation exchange capacity (ECEC), is the sum of exchangeable Ca²⁺, Mg²⁺, K⁺, Na⁺, and unbuffered salt-extractable acidity (Coleman et al., 1959).

Tolerance to Al differs significantly among plant species and cultivars within species. Reviews of field lime trials suggested that cassava yields were not depressed by %Al saturation values of <75%, whereas best yields for most trials with cotton, mung bean, and wheat were at 0% Al saturation; however, critical Al saturation levels among trials with different varieties ranged from 0% to 40% with corn and soybean and 0% to 60% with upland rice (Osmond et al., 2007). There are various proposed mechanisms of Al tolerance, which can be both internal and external to plants (Taylor 1991; Kochian, 1995). Internal tolerance involves detoxification after Al3+ is absorbed, whereas external mechanisms imply the prevention of Al3+ uptake and transport. Proposed exclusion mechanisms by various investigators include immobilization of Al3+ at the cell wall, low root CEC, selective permeability of the plasma membrane, changes in rhizosphere pH, exudation of Al-chelating compounds, and Al3+ efflux. Internal mechanisms may also include chelation of Al3+, compartmentalization in vacuoles and Al-tolerant enzymes (Silva et al., 2002).

12.3.3 Manganese Toxicity

Acid soils with large contents of Fe and Al oxides often contain quantities of Mn that are toxic to plants (Kamprath, 1984). Plant growth is reduced through excess accumulation of Mn in aboveground plant tissues. Plant symptoms of Mn toxicity vary among species, but include marginal chlorosis and necrosis of leaves, leaf puckering and necrotic spots on leaves (Foy, 1984). Soil solution levels of Mn⁺² are difficult to predict, because they are influenced by total soil Mn content, soil pH and redox potential. Although solubility decreases with increasing pH, Mn toxicity may occur above a soil pH of 5.5 under the appropriate reducing conditions (Sumner and Yamada, 2002). Improved plant growth upon liming soils above pH 5.5, where soil solution and exchangeable Al³⁺ are reduced to essentially zero, is often associated with the alleviation of Mn toxicities (Kamprath, 1984; Sumner and Yamada, 2002).

12.3.4 Calcium and Magnesium Deficiencies

Acid soils with high %Al saturation have limited amounts of Ca²⁺ and Mg²⁺ in either the exchangeable form or in the soil solution. The supply of adequate Ca2+ and Mg2+ for normal plant growth may also be constrained in soils with low CEC due to their limited capacity to retain these cations (Kamprath, 1984). An external supply of Ca2+ is essential for normal root development (Rios and Pearson, 1964; Ferguson and Clarkson, 1976; Clarkson, 1984). The addition of 0.1 cmol, Ca kg-1 (20 mg Ca kg-1) to an Oxisol initially containing 0.02 cmol, Ca kg-1 (4 mg Ca kg⁻¹) increased wheat seedling length by over 50%, regardless of whether the Ca was supplied as lime, calcium chloride or calcium phosphate (Ritchey et al., 1983). In a review of lime experiments in the tropics, Kamprath (1984) suggested that an exchangeable soil Ca level of 1.0 cmol, kg-1 as a minimum value for good plant growth. Plant growth responses to Mg are often linked to conditions of low soil exchangeable Mg2+ and/or less than 5% Mg saturation of the CEC and pH values ≤5 (Adams, 1984; Kamprath and Foy, 1985; Kamprath and Smyth, 2005).

The susceptibility of peanut to Ca deficiency is associated with its below ground fruit development. The fruit absorbs most of its Ca from the surrounding soil solution. In the absence of adequate ambient soil Ca, shelling percentage is reduced due to poor fruit development (Cox et al., 1982; Adams, 1984). Soil Ca is often supplemented for peanut by applications of lime and gypsum.

12.3.5 Phosphorus and Molybdenum Deficiencies

Investigations regarding improvement of soil P solubility with liming provide conflicting results, as indicated in several reviews of the subject (Kamprath and Foy, 1985; Sumner and Yamada, 2002). However, there is general agreement that neutralization of exchangeable Al³⁺ increases root growth, exploration of a greater soil volume, and access to more soil P. In acid soils Al³⁺

Soil Acidity and Liming 12-3

at the root surface precipitates P and reduces P transport to plant tops; neutralization of Al ³⁺ by liming increases transport of P to plant tops (Kamprath and Smyth, 2005).

Molybdenum is an essential nutrient for N fixation in legumes. The availability of soil Mo is a function of Mo content, pH and MoO₄²⁻ absorption by hydrous oxides of Fe and Al (Adams, 1984; Kamprath and Foy, 1985). In a review of lime and Mo experiments, soil solution Mo increased two- to threefold as soil pH was increased up to values of 6–7; likewise, soybean yields without Mo treatment increased with liming and approached yields of seed Mo treatments at pH values above 6 (Sumner and Yamada, 2002). With Mo added via seed treatments, there was no soybean yield response to lime above pH values of 5.3–5.5 where most of the exchangeable Al⁺³ is neutralized. Increased solubility of Mo with increasing pH is attributed to OH⁻ displacement of adsorbed MoO₄²⁻ on hydrous oxides of Fe and Al (Barrow, 1978).

12.4 Lime Requirement Methods

For extensive reviews and comparisons between lime requirement methods, the reader is referred to articles by van Lierop (1990), Sims (1996), and Sumner (1997). Some of the most commonly used methods are discussed herein.

12.4.1 Soil-Lime Incubations

Increasing rates of lime are mixed with fixed quantities of soil and equilibrated in a moist state for weeks or months. Lime required to achieve a given soil pH or exchangeable Al³⁺ level can be related to measurements of other soil chemical and physical attributes. Although time and costs of this method are not conducive to lime recommendations via routine soil testing, it is widely used to test and verify most of the rapid lime tests in current use across a number of soils with a range of chemical and physical characteristics within a given region of interest.

12.4.2 Buffer pH Methods

A given volume of a buffer solution is equilibrated with a fixed weight or volume of soil, and pH of the soil–buffer mixture is measured. The molarity of the buffer solution is known and the decrease in its pH, after mixed with soil, is a measure of the soil acidity that must be neutralized by a base in order to achieve a targeted soil pH.

Buffer pH methods used to determine lime requirements in different regions of the United States are described in Table 12.1. Each method was developed for representative soil types in a given region. The composition of the buffer solutions is different and has pH values ranging from 6.6 to 8.0. The targeted soil pH values after liming range from 6.0 to 7.0 among the various methods and the amount of lime required for a pH decrease of 0.1 in the buffer-soil mixture, relative to that of the initial

TABLE 12.1 Characteristics of Buffer pH Methods Used to Determine Lime Requirements in the United States

		Target		Lime/0.1 Buffer pH Decrease
Method	Buffer pH	Soil pH	Intended Soil Use	ton CaCO ₃ ha ⁻¹
Adams and Evans	8.0	6.5	Low CEC Ultisols	0.1
Mehlich	6.6	6.0	Neutralize exch. Al ⁺³ , Ultisols	0.16

buffer solution, ranges from 0.1 to 0.6 ton of CaCO₃ ha⁻¹. Several investigators have recently proposed modifications to existing methods (Huluka, 2005; Sikora, 2006; Sikora and Moore, 2008) or new buffer methods (Liu et al., 2005).

12.4.3 Exchangeable Aluminum

Lime requirements are based on the amount of exchangeable Al³⁺ extracted from soils with neutral unbuffered salt solutions such as KCl (Kamprath, 1970). Adding lime to mineral soils on an equivalent basis to the amount of exchangeable Al³⁺ raises soil pH to 5.3–5.6 and reduces soil solution Al³⁺ concentration and exchangeable Al to near zero (Kamprath, 1984; Sumner and Yamada, 2002). Lime neutralizes exchangeable acidity, but also reacts with the nonexchangeable acidity that includes Al bound to organic matter and H associated with carboxyl groups of organic matter, hydroxy Al, and hydrated oxides of Fe and Al. Therefore, lime requirements to achieve 0% Al saturation of the ECEC, based on exchangeable soil acidity, include a lime equivalence factor that is greater than 1.0 and usually in the range of 1.5–4.0 (Kamprath, 1984; Sumner, 1997).

There are several proposed modifications of the basic lime requirement determination based on exchangeable Al. Cochrane et al. (1980) proposed the following adjustment that accounts for differential acid tolerance among crops and cultivars:

$$CaCO_{3} \ equivalent \ (ton \ ha^{-1}) = LF \Bigg[Al - \frac{TAS(Al + Ca + Mg)}{100} \Bigg]$$
 (12.1)

where

LF is the product of 1.5 equivalents of CaCO₃/equivalent of exchangeable Al plus the conversion to a 20 cm layer for a hectare of soil

Al, Ca, and Mg are exchangeable cations extracted with a neutral unbuffered salt

TAS is the %Al saturation tolerated by the crop or cultivar

This approach seeks to only neutralize the quantities of exchangeable Al that exceed the %Al saturation tolerated by the crop. Although useful in regions where lime materials are expensive, data on exchangeable Ca and Mg, and %Al saturation tolerated by the intended crop must also be known in addition to soil exchangeable Al.

In soils with low ECEC, lime required to neutralize the exchangeable acidity may not be sufficient to correct Ca and Mg deficiencies. Therefore, lime requirements may include considerations of minimum targets for soil exchangeable Ca and Mg as illustrated by the following adjustment proposed by Sousa and Lobato (2002) to ensure that soil Ca + Mg achieves a value of 2 cmol₂ dm⁻³ after liming:

$$CaCO_3$$
 equivalent (ton ha^{-1}) = 2(Al) + (2 - (Ca + Mg))

(12.2)

12.4.4 Comparison of Lime Requirement Methods

Given the combination of soil factors associated with a potential acidity constraint, Sumner and Yamada (2002) proposed grouping acid soils into two general categories: soils with pH values <5.2–5.4 where Al and Mn toxicities are the primary constraints to crop growth, and soils with pH values >5.4 where liming impacts crop growth through improved availability of nutrients, namely Ca, Mg, Mo, and P. In the first category, increasing soil pH via liming resolves the toxicity problems, whereas nutrient inputs without liming are an alternative remedial strategy to nutrient availability problems in the latter group. An understanding of the types of acidity constraints in the soils of interest can help in determining the most appropriate remedial strategy.

Differences in soil factors contributing to an acidity constraint and crop species/cultivar tolerances to Al and Mn toxicities reduce the likelihood that a given target pH value can be used to estimate lime requirements under a variety of circumstances. Therefore, it is important that lime requirement methods should be calibrated with crop performance data under field conditions for the representative crops and soil types of interest in a given region (Sumner, 1997). Liming mineral soils to a pH value of 6 ensures neutralization of exchangeable Al (around pH 5.4-5.6) and reduces the frequency for repeated applications of lime as the soil re-acidifies through N fertilizer inputs and plant secretion of H⁺. Unless Mn toxicity is an issue, liming of acid soils to pH values above 6 will decrease the solubility of Cu, Fe, Mn, and Zn and potentially induce their deficiencies in soils where availabilities are adequate at lower pH values (Kamprath, 1971; Lucas and Knezek, 1972). Modest levels of soil acidity (pH values of 5.0-5.5) can also have economically beneficial impacts by reducing the incidence of pests and diseases such as soybean cyst nematode (Heterodera glycine) (Garcia et al., 1999) and scab disease (Streptomyces scabies) in potato (Keinath and Loria, 1989).

12.5 Lime Material Characteristics and Application

Various materials derived from natural deposits or industrial by-products can be used for liming. Calcium carbonate (calcitic limestone) and calcium-magnesium carbonate (dolomitic limestone) are frequently used crystalline compounds from natural deposits. Marls are soft, unconsolidated calcium carbonates that may contain some clay impurities. Calcium oxide (burnt or quick lime) and calcium hydroxide (hydrated lime) are white powders that are caustic when wet and difficult to mix uniformly with soil. Basic slag (calcium silicate) is a by-product of the steel industry often containing appreciable amounts of Mg and P. Several factors to consider when selecting and applying lime materials are described in the following sections.

12.5.1 Neutralizing Value

The neutralizing value represents the amount of acid neutralized by a unit weight of lime material. Pure calcium carbonate serves as a standard and has the calcium carbonate equivalent (CCE) value of 100%. The CCE values of several pure liming materials are given in Table 12.2. Most liming materials have impurities, which reduces their CCE value. Lime requirement estimates are often based on 100% CCE and the actual application rate needs to be adjusted for the CCE value of the selected lime material.

12.5.2 Fineness of Liming Materials

Upon contact with acid soils, lime particles dissolve and release Ca^{2+} and HCO_3^- , which leads to neutralization of H^+ and Al^{3+} . The reaction rate depends on the surface area of the lime particles in contact with the soil. Therefore, it is desirable that small particles are close together so that their zones of neutralization overlap in a short time.

Calcitic and dolomitic limestones are ground to increase the number of particles per unit of soil. Most ground lime materials contain a range of particle sizes from very fine to sand-sizes, which comply with state or province regulations on particle size distribution. A fineness factor for the lime material is the sum of the products of percentages of lime material in each size fraction and its corresponding efficiency factor. Depending on regional regulations, fractions greater than a certain size have

TABLE 12.2 Neutralizing Value (CCE %) of Pure Liming Materials

Material	% CaCO ₃ Equivalence
Calcium carbonate, CaCO ₃	100
Calcium-magnesium carbonate, CaMg(CO ₃) ₂	109
Calcium oxide, CaO	179
Calcium hydroxide, Ca(OH) ₂	135
Calcium silicate, CaSiO ₃	86

Soil Acidity and Liming 12-5

an efficiency factor of zero (e.g., >2 mm) and this value increases to a maximum of 1.0 with decreasing particle fineness (e.g., <0.4 mm) (Havlin et al., 2005). Calcitic limestones are softer than dolomitic limestones; thus, a given size fraction of the former dissolves at a faster rate (Kamprath and Smyth, 2005).

12.5.3 Effective Calcium Carbonate Rating

Effective Ca carbonate rating (ECC) is the product of the CCE and fineness factor for the liming material. The selection among available lime materials often involves comparing costs of sources per unit ECC and whether Mg inputs (via dolomitic limestone) are needed.

12.5.4 Lime Incorporation into the Soil

Lime should be mixed with the volume of soil to which one intends to neutralize acidity. In conventional tillage systems, lime recommendations often assume a soil depth of 15–20 cm. Thorough mixing can be achieved by broadcasting and incorporating half of the lime by disk or plow, followed by inversion and broadcasting and disking the remainder. In no-till systems, however, lime is surface applied and initial acid neutralization will be limited to the 0–5 cm soil depth. Surface applications without incorporation of lime rates to neutralize soil acidity in a 15–20 cm soil depth can lead to excessively high soil pH values and associated nutrient deficiencies in the 0–5 cm soil depth.

The effectiveness of surface-applied lime in ameliorating subsoil acidity below the 0-5 cm depth is an important consideration in no-till systems, especially when root elongation is constrained and crops lose access to soil reserves of water and nutrients. Sumner (1995) has reviewed an extensive collection of investigations regarding amelioration of subsoil acidity through surface application of lime and gypsum. The investigations entail a variety of soil types, climatic regimes, and rates of lime or gypsum. Likewise, the subsoil depth to which lime or gypsum moved was quite variable, although the process of detectable movement was gradual and entailed months and years after surface applications. In some instances, the changes in subsoil acidity consisted of increased exchangeable Ca and Mg without improvements in soil pH values. Although increases in solution Ca2+ concentration at constant pH can ameliorate Al3+ rhizotoxicity to some extent (Alva et al., 1986; Horst, 1987; Wright and Wright, 1987; Noble et al., 1988; Sanzonowicz et al., 1998), absence of an increased subsoil pH suggested that alkaline anions (HCO₃⁻ and/or OH⁻) were not associated with the downward transport of basic cations from the surface applied lime (Sumner, 1995). In cases where subsoil pH also increased with downward movement of Ca2+ and Mg2+, Sumner (1995) proposed two potential processes: (a) downward movement of NO₃- and plant secretion of OH- when NO₃- uptake from subsoils leads to an excess of anion over cation uptake; and (b) complexation of toxic Al3+ by downward movement of soluble organic components. The former process supports frequent observations that subsoil Ca2+, Mg2+, and pH increased more rapidly when surface

applications of lime were complemented with acidifying fertilizers. The trade-off, however, is a faster acidification of the surface soil when ammoniacal N sources are used.

Several investigators have compared the residual effects of an initial surface application of lime with and without supplementary lime applications in succeeding years (Blevins et al., 1978; Edwards and Beegle, 1988; Godsey et al., 2007). In all cases, lime rate had a greater effect than frequency of lime application in reducing acid characteristics of the subsoil. Nevertheless, frequent surface applications of lime in no-till systems will avoid detrimental effects on crop growth through acidification of the surface soil layers.

13.1 Introduction

13.1.1 Soil Fertility: A Modern Definition

Soil fertility is a scientific discipline that integrates the basic principles of soil biology, soil chemistry, and soil physics to develop the practices needed to manage nutrients in a profitable, environmentally sound manner. Historically, the study of soil fertility has focused on managing the nutrient status of soils to create optimal conditions for plant growth. Fertile, productive soils are vital components of stable societies because they ensure that we are able to grow the plants needed for food, fiber, animal feed and forage, medicines, industrial products, energy, and for an aesthetically pleasing environment. Beyond management of soil nutrients, the study of soil fertility rests on two other fundamental principles. First, optimum nutrient status alone will not ensure soil productivity. Other factors such as soil moisture and temperature, soil physical condition, soil acidity and salinity, and biotic stresses (disease, insects, weeds) can reduce the productivity of even the most fertile soils. Second, modern soil fertility practices must stress environmental protection as well as agricultural productivity; that is, we must prevent the pollution of our soils, air, and water as we strive to optimize the nutrient status of soils for plant growth.

13.1.2 Soil Fertility Evaluation: Purpose, General Principles, and Practices

Soil fertility evaluation is a central feature of modern soil fertility management. The fundamental purpose of soil fertility evaluation has always been to quantify the ability of soils to supply the nutrients required for optimum plant growth. Knowing this, we can optimize the nutrient management practices needed to achieve economically optimum plant performance. Related, equally important goals are as follows: (1) to identify other factors that reduce soil productivity (e.g., acidity, salinity, elemental phytotoxicity) and (2) to determine if the intended use of the soil may negatively impact the quality of our environment.

The general principles and practices of soil fertility evaluation are derived from or influenced by many other disciplines (e.g., soil science, plant physiology, plant genetics, crop science, plant pathology, entomology, climatology, hydrology, statistics). This chapter, and other publications (Black, 1993; Tisdale et al., 1993; Foth and Ellis, 1997; Havlin et al., 2004), describes these principles and practices in great detail. At heart, however, we seek to evaluate the fertility of a soil by observations and tests and then to use this information to predict the response of plants, and the larger environment, to our nutrient management efforts. The actual practices that constitute soil fertility evaluation include an impressive array of field and laboratory diagnostic techniques and a series of increasingly sophisticated empirical and/or theoretical models that quantitatively relate these indicators of soil fertility to plant response. Diagnostic techniques include long-standing practices, such as chemical and biological soil tests, visual observations of plant growth for nutrient deficiency or toxicity symptoms, and chemical analyses of plant tissues. New approaches include passive or active optical sensing technologies and geographic information systems (GIS) that facilitate landscape scale, site-specific assessments of soil fertility. Computerized expert systems allow us to rapidly relate these indicators of soil fertility to quantitative or qualitative assessments of plant performance (e.g., yield, composition, quality, color, health) and thus to rapidly adjust soil management practices for the most efficient use of nutrients. These advances in computing, GIS, and sensing technologies have allowed us to better describe and address the temporal and spatial variability of soil fertility.

13.1.3 Soil Fertility Evaluation for Agricultural and Nonagricultural Systems

The study of soil fertility evolved within ecosystems devoted primarily to the production of agricultural crops, particularly plants grown for food, forage, fiber, and industry. Tisdale et al. (1993) traced the relationship of soil fertility management to food production as far back as 2500 BC. The importance of soil fertility to world agriculture continues today as a spiraling world population and a diminishing arable land base create unprecedented pressures on scientists and practicing agriculturalists to produce more food per unit area of land than ever before. Advances in plant genetics and breeding and other agricultural technologies (e.g., irrigation) are increasing agricultural productivity. However, higher crop yields mean greater depletion of soil nutrient supplies, which eventually must be balanced by increased nutrient inputs to maintain the fertile soils needed by our societies. Given this, it is apparent that soil fertility evaluation will play an increasingly important role in the future of global agriculture as we seek to identify new lands that can be brought into production and to maximize the production from existing soils. Land uses other than traditional "production" agriculture also require a thorough, in-depth evaluation of soil fertility for maximum economic and environmental efficiency. Examples are horticultural systems, disturbed lands needing reclamation, and soil conservation and remediation practices.

Horticulture includes an extremely diverse range of situations where nutrients must be managed, often quite intensively. Vegetables for fresh market and processing, greenhouses and nurseries growing ornamental and vegetable plants for urban areas, golf courses, public gardens, parks, athletic facilities, and the managed landscapes around commercial businesses, governmental offices, and cities are only a few examples. The types of plants and growth media ("soilless" growth media are often used for horticultural plants) common to these situations are staggering in breadth and variability, challenging the ability of scientists to provide a systematic process for soil fertility evaluation.

Land reclamation can be equally diverse in terms of the nature of the growth media and the types of plants. Soils at land reclamation sites (e.g., surface mining, highway construction, landfills) are often highly disturbed by human activity and possess extremely unfavorable chemical and physical characteristics, including very low soil fertility. In many cases the soils used to revegetate disturbed lands are in fact subsoils, geologic materials, or low-quality soil materials imported from nearby borrow pits.

In other cases, "synthetic" soils, created from by-products such as biosolids, coal ash, composts, and poor quality soil must be used. Evaluating the fertility status of soil-like materials such as these, with reference to the growth of grasses, shrubs, and trees must often proceed in the absence of a database relating soil nutrient status and/or other soil properties to plant performance.

Related, but slightly different problems are faced when evaluating the fertility of soils used for conservation purposes, such as grassed waterways, terraces, buffer strips, constructed wetlands, and wildlife habitats. In cases such as these, where the goal is not maximum yield but a stable vegetative cover, the objective may often be low to moderate soil fertility, not agronomically optimum nutrient values. Preventing excessive growth of invasive species is also usually a goal in these settings, and many invasive plants become more competitive if soil fertility is high. Finally, the need to ensure optimum soil fertility in soil remediation programs is a new, but increasingly important aspect of soil fertility evaluation. The goals of these programs may be enhancing microbial degradation of an organic contaminant, such as an oil spill, or phyto-remediation (plant-based remediation of a contaminated soil) of an inorganic contaminant, such as cadmium (Cd), lead (Pb), or zinc (Zn) from the soil near an industrial site (Berti and Cunningham, 1994; McCutcheon and Schnoor, 2003).

13.1.4 Soil Fertility Evaluation: Environmental Issues

Environmental quality is inextricably linked with soil fertility. Just as it is essential that we manage soils to optimize plant productivity, it is equally important to manage soil fertility to avoid or minimize the pollution of our waters, atmosphere, and food chain. A wealth of scientific research has clearly documented that some essential plant nutrients can also contribute to environmental problems. Nitrogen (N), arguably the most important plant nutrient, is known to cause human and animal health problems if nitrate-N (NO₃-N) leaches to ground waters used for drinking water supplies. Ammonia-N (NH3-N) from fertilizers and animal manures can volatilize to the atmosphere as a gas and, upon redeposition in rainfall, cause soil acidification in forest ecosystems. Nitrous oxides (NO_x) produced by the microbial conversion of NO₃-N in soils to gaseous forms of N (NO, N₂O) have been implicated in ozone depletion and global warming. Eutrophication of surface waters, defined as "...enrichment of surface waters by plant nutrients... regarded as a form of pollution as it restricts the potential uses of impacted water bodies" (Foy and Withers, 1995), can be caused by phosphorus (P) and N entering these waters in soil erosion and runoff, or, in the case of NH₃-N by aerial deposition in rainfall. Soil salinity problems can result when the plant nutrients calcium (Ca), magnesium (Mg), potassium (K), sulfate-sulfur (SO₄-S), and chloride (Cl) or nonessential elements such as sodium (Na) accumulate to excess in soils, particularly in arid regions.

Efforts to enhance soil fertility by use of society's wastes or by-products as nutrient sources can also directly or indirectly

affect environmental quality. Modern industrialized societies face increasing pressures to land apply wastes to avoid the costs and undesirable environmental impacts of landfilling and incineration. Lesser developed countries often must use wastes and wastewaters as fertilizers and for irrigation because of a lack of resources, equipment, and infrastructure. For example, the use of municipal biosolids (e.g., sewage sludge, compost) as soil amendments is beneficial because it recycles plant nutrients while building soil organic matter. However, this practice is carefully regulated in most countries because biosolids may contain nonessential elements that can be phytotoxic or can accumulate in the food chain, impacting human, animal, or ecosystem health. Additionally, most land application programs for biosolids (and animal manures) base application rates on the amount of N needed for optimum crop yields. However, the unfavorable N:P ratio in most organic wastes, relative to the N:P ratio in harvested crops, usually means that P accumulates in waste-amended soils to concentrations much higher than required for crop production. This creates an environmental dilemma because the beneficial use of organic wastes as N sources causes the build-up of P in soils and the likelihood that significant amounts of P will be lost to surface waters in erosion and runoff (see Section 11.2). Other municipal, agricultural, or industrial by-products that have been shown to have beneficial effects on some aspect of soil fertility and/or productivity often create similar dilemmas. Materials such as papermill sludges, municipal composts, wood ashes, coal combustion by-products (e.g., flue gas desulfurization gypsum, coal fly ash) are all sources of plant nutrients. However, if managed improperly, they can also create unfavorable soil pH values, excessive soluble salts, and cause microbial or chemical immobilization of plant nutrients.

Soil fertility evaluation is more complex today because of the need to balance productivity and environmental protection for a wider and more diverse range of land uses, as illustrated conceptually in Figure 13.1. This chapter presents a critical analysis of

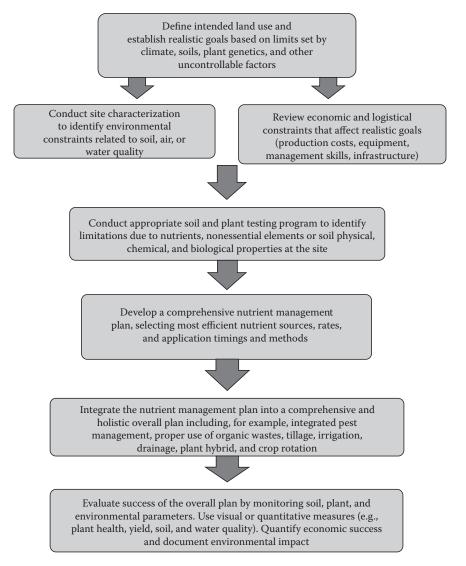

FIGURE 13.1 Conceptual summary of the process of soil fertility evaluation.

the major techniques used in soil fertility evaluation—soil and plant testing, focusing not only on current practices but on the recent advances in science, technology, and interpretive philosophies that will shape soil fertility evaluation in the future.

13.2 Soil Testing

13.2.1 Soil Testing: Historical Overview

Soil testing is defined as "...rapid chemical analyses to assess the plant-available nutrient status, salinity, and elemental toxicity of a soil...a program that includes interpretation, evaluation, fertilizer and amendment recommendations based on results of chemical analyses and other considerations" (Peck and Soltanpour, 1990). The use of soil testing represents perhaps the most significant practical application of our knowledge of soil science to land use management and should be viewed fundamentally as an interpretive process, not simply as a series of laboratory methods. The purpose of soil testing is to provide a quantitative basis to guide soil management decisions, usually, but not always, for agricultural systems (e.g., agronomy, horticulture, silviculture) where plant growth and performance (yield) are the ultimate measures of success. Soil testing has applications to other systems as well; particularly to those where the goal is protection of human health or the environment. Advancing soil testing in nonagricultural systems requires a thorough review of the technical aspects of soil testing and the basis by which we evaluate its success, since plant production is not the issue of greatest importance.

Early efforts at soil testing began in the nineteenth century but systematic studies of the relationship between soil testing and plant growth did not occur until the 1920s. As with soil fertility in general, soil testing evolved within an agricultural setting; hence, its principles and practices have been markedly influenced by the needs and interests of production agriculture. The original purpose of soil testing was rather straightforward to determine if soils were deficient in nutrients and, based on field studies of crop response to fertilizers and manures, to make recommendations for the nutrient rate, source, and method that would most effectively overcome the limitations caused by the nutrient deficiency. Organized soil testing programs began to be established in the United States in the late 1940s as chemical soil tests were developed that could rapidly assess nutrient availability in soils. The broader infrastructure of soil testing originated first with universities, where research and Extension scientists conducted the laboratory, greenhouse, and field studies needed to verify the accuracy and reliability of soil test methods. Following close upon these studies was the educational aspect of soil testing-publications that described how to test soils and report forms that provided users (primarily farmers) with results and recommendations. Today soil testing is an international activity operating in both the public and private sectors. In the United States, numerous regional and national soil testing organizations, often including public and private soil testing laboratories, are in place to review and revise soil testing methods, update soil test interpretations and recommendations, and ensure the analytical proficiency of soil testing laboratories. Information on the activities and publications of these vitally important advisory and overview groups is available from the web sites of the Soil Science Society of America (SSSA) (https://www.soils.org/), the Soil and Plant Analysis Council (http://www.spcouncil.com/), and the North American Proficiency Testing Program (http://www.naptprogram.org/).

13.2.2 Soil Testing: Assessing Elemental Availability in Soils

One of the fundamental tenets of soil testing is that only a proportion of the total quantity of an element in a soil will be available for assimilation by a biological organism. This means that measuring total elemental concentration in soils is usually of little value. Instead we must have testing methods that can extract (complex, dissolve, desorb, exchange, hydrolyze) a percentage of the total soil nutrient pool that is proportional to the quantity that will become available to the organism of interest during the time period of concern. The term labile is often used to describe the chemical and biological forms of an element that are in rapid equilibrium with the soil solution and are thus most likely to be available for biological assimilation. A similar term, bioaccessible, is often used when the primary interest is in testing contaminated soils for potentially toxic elements, particularly metals such as arsenic, copper, chromium, and lead, where the main concern is human exposure via ingestion or dermal contact. Much of soil testing research has focused on the development of chemical extracting solutions that can selectively remove labile and bioaccessible elements from the soil in a rapid and reproducible manner.

13.2.2.1 Assessing the Availability of Essential and Nonessential Elements

Insofar as soil fertility is concerned we are most interested in the availability of the 13 elements known to be essential for plant growth that are primarily obtained from soils (N, P, K, Ca, Mg, S, B, Cl, Cu, Fe, Mn, Mo, Zn) as opposed to those obtained from air (C, O) and water (H, O). When we consider human, animal, and environmental health, we have two other concerns. First is the potential environmental impact of essential plant nutrients found in soils that may be transported to other ecosystems (e.g., soil P movement to surface waters). Second is the fate of essential and nonessential elements added to soils in fertilizers or other soil amendments (biosolids, composts, industrial by-products, manures) that may impact human health should they enter the food chain, drinking water supplies or natural ecosystems or become toxic to plants if they accumulate to high concentrations in soils. The nonessential elements of greatest concern are aluminum (Al), arsenic (As), barium (Ba), cadmium (Cd), chromium (Cr), lead (Pb), mercury (Hg), nickel (Ni), and selenium (Se). Potentially toxic essential elements are Cu, Mo, and Zn.

The most common means to assess the availability of elements in soils is with chemical soil test extractants, which are typically

dilute solutions or mixtures of acids, bases, salts, and chelates. Biological techniques (e.g., bioassays based on microbial growth) have been used to a limited extent but are generally too expensive and time-consuming for routine use. The most effective concentrations and relative proportions of the reagents in a chemical extracting solution were usually determined empirically by comparison of the amount of an element extracted from the soil with some type of biological response (usually yield) by a target organism (usually a plant). The nature and diversity of chemical solutions used in soil testing is illustrated by comparing the Mehlich 1 soil test, a dilute mixture of two strong acids $(0.05\,\mathrm{M\ HCl} + 0.0125\,\mathrm{M\ H}_2\mathrm{SO}_4)$, the ammonium bicarbonatediethylenetriaminepentaacetic acid (AB-DTPA) soil test, a dilute combination of a base (1 M NH₄HCO₃) and a chelating agent (0.005 M DTPA), and the Bray P₁ soil test, a dilute mixture of a strong acid (0.025 M HCl) and a complexing ion (0.03 M NH₄F).

Soil testing extractants developed for plant nutrients have also been used, with some success, to assess the risk of plant uptake of nonessential elements (O'Connor, 1988, Risser and Baker, 1990; Gaskin et al., 2003; Sukkariyah et al., 2005) or loss of these elements in surface runoff (Zhang et al., 2003). Other soil testing methods are also used for these elements, although not to measure biological availability. Examples include a method to measure total sorbed metals that is often used to monitor the accumulation of elements in the soil up to some defined regulatory limit (EPA-3050; U.S. Environmental Protection Agency, 1986) and the toxicity characteristic leaching procedure (TCLP), sometimes used to determine if a soil is sufficiently polluted with an element or organic compound to be considered a hazardous waste. Recent advances in environmental soil testing for some metals (As, Cd, Pb, Zn) have used extracting solutions that simulate the biological activity within the human digestive system, referred to as the physiologically based extraction test (PBET) (Ruby et al., 1996; Fendorf et al., 2004; Brown et al., 2007).

13.2.2.2 Influence of Soil Properties and Environmental Conditions on Elemental Availability

One of the major challenges in the evaluation of soil fertility is the need to develop tests (chemical or otherwise) that can estimate nutrient availability in soils of widely differing biological, chemical, and physical properties. Decades of soil science research have proved that the availability of elements in soils depends both on soil properties that are essentially permanent (e.g., the percentages of sand, silt, and clay, oxides of Fe and Al, carbonates, and organic matter) and on those that are more sensitive to natural and anthropogenic inputs (pH, cation exchange capacity [CEC], oxidation-reduction status). Elemental availability can also be markedly affected by broader soil properties (drainage class, nature of soil horizons, slope) and by the soil environment (aeration, moisture, temperature). Therefore, if we wish to estimate the present availability of essential and/or nonessential elements in a given soil, and how this availability will change following some management practice, we must also have a good understanding of the basic properties of that soil and of the environmental conditions likely to be present during the time interval of interest.

Two approaches are used to integrate soil properties and environmental conditions with elemental availability provided by soil testing. First, we can directly test soils for some of these properties and use this information to modify our assessment of biological availability. The most common examples of this are soil pH and organic matter content; other parameters (e.g., CEC, texture, oxides, carbonates) are usually too time-consuming to measure routinely. Second, we can obtain information on soil properties that are difficult to measure and on environmental conditions simply by asking a few key questions of the individual submitting the soil sample for analysis. Knowledge of geographic location, soil series, drainage class, slope, and historical information on previous soil management practices (e.g., fertilization, liming, crop rotation) can be invaluable when evaluating soil productivity and thus crop nutrient requirements. Our ability to integrate information such as this into management recommendations has markedly improved due to the now widespread use of computers in soil testing and with the increased ease of using GIS that are capable of "layering" different data bases to provide a more holistic view of the relationship between soil fertility and land use.

13.2.3 Soil Testing: Overview of the Major Components

All modern soil testing programs have four basic components: (1) soil sample collection, handling, and preparation; (2) soil analysis; (3) interpretation of analytical results; and (4) recommendations for action. For soil testing to be successful, each component must be conducted properly, keeping the overall objective (e.g., plant production or environmental protection) firmly in mind, and with an awareness of the potential sources of error that can occur at each step.

13.2.3.1 Soil Sample Collection and Handling

Collection of a sample that is representative of the entire area of interest, whether it is a farm field, a lawn or garden, or a severely disturbed soil at a construction or mining site, is the most important step in any soil testing program. Proper handling of the sample, once collected, is also important to avoid contamination or changes in elemental concentrations due to improper storage and/or the use of incorrect techniques to prepare the soil sample for analysis (drying, grinding, sieving). An effective soil sampling and handling program must be based on an understanding of the natural and anthropogenic sources of soil variation, the proper method of sample collection (depth, time of year, sampling tools), and the sources of error in sample handling and preparation.

13.2.3.1.1 Understanding and Compensating for Variability

A high degree of natural variability in soil chemical and physical properties can exist even within a very small area. The origin of this variability is the soil forming process in which parent material, climate, relief (topography), biota, and time act together to produce soils that are fundamentally different, not only in terms of topsoil properties, but throughout the entire soil profile. Sample collection should reflect this natural variability, to the extent that it is likely to significantly influence the intended use of the soil. In some cases the differences between adjacent soil series in a large field may be pronounced and require not only different soil samples, but entirely different soil and crop management practices. In other situations differences are minor and collecting additional samples and/or altering management practices is not economically justifiable. Information on the spatial distribution of soil series in an area is available in soil surveys such as those published and now available on the internet (http://soils.usda.gov/survey/printed_surveys/) by the U.S. Department of Agriculture's Natural Resources Conservation Service (USDA-NRCS). Internet access to soils information, at least in the United States has increased significantly in the past decade and much useful information is now available at the NRCS "Soil Data Mart" (http://soildatamart.nrcs.usda. gov/). The Soil Data Mart can quickly allow users to determine where soil tabular and spatial data are available and then to download these data and a variety of reports for individual soil survey areas. Consulting soil surveys is a first step in identifying natural sources of variability to consider in a soil sampling program. A simple follow-up to reviewing these soil surveys is to visually inspect the areas of interest, particularly during periods of plant growth or major seasonal changes in climate, to determine how natural soil variability is affecting land use. New technologies are now available to integrate soil survey information and qualitative data on soil spatial variability into GIS-based land use planning including the use of remote sensing and global positioning systems (GPS), to link soil sample location to soil series. For agronomic crops yield, monitoring devices can now be installed on harvesting equipment, providing a spatially based data set that relates soil fertility, soil series, and plant performance (see Section 13.4). Natural variation can often be overshadowed by the variability in soil fertility caused by human activities. Many soil management practices, such as the method of fertilizer or organic waste application, the tillage method, land leveling for irrigation, terracing, and even the year-to-year selection of what plants will be grown and where, can produce marked differences in soil nutrient status and other soil properties. These differences can be even more pronounced in nonagricultural settings, such as land reclamation projects, where soil disturbance can be severe and by-products may be used as soil amendments at unusually high rates. It is also important to remember that anthropogenic as well as natural soil variability can occur in three dimensions. For example, changing from conventional tillage to no-tillage can result in surface accumulation of P and a decrease in pH at the soil surface as well. Therefore, such factors should be accounted for when designing a soil sampling program. Similarly, nutrient management practices that involve subsoil tillage or injection of soil amendments (e.g., lime, fertilizer, manures) can extend spatial variability below the topsoil, a factor that should not be ignored in the soil sampling process.

Many other examples could be cited to make the point that spatial variability in soil properties, natural or anthropogenic, is inevitable. What is more important, however, are the practices that can be used to compensate for any known source of variability. James and Wells (1990) suggested that soil sample collection basically occurs under either uniform or nonuniform conditions and that sampling techniques should reflect this. Uniform fields are those that are reasonably similar in physical properties (e.g., slope, aspect, drainage, soil series,) and management practices (e.g., crop rotation, fertilizer/manure management history, tillage, irrigation). In many agricultural settings this is a rather common scenario. The proper approach to use for uniform fields is to collect a random, composite sample. This is normally done by following a "zig-zag" path across the area to be sampled, collecting enough soil samples to minimize the influence of any localized nonuniformity (Figure 13.2). Typically this involves collecting about 25-30 separate soil cores from a uniform area <8 ha (~20 acres), ensuring that field corners and edges are included in the sample. Individual soil cores are combined into one composite sample that represents the entire area by crushing and mixing and the composite sample is submitted for analysis.

Nonuniform fields were defined by James and Wells (1990) as those with a high degree of either macro-variation (significant variation between sample points separated by >2 m) or mesovariation (significant variation between sample points separated by 0.05–2 m). For areas with high macro-variation a nonrandom sampling process must be followed to characterize the average value for the soil properties of interest and to understand the spatial location of extreme values. This prevents skewing of average soil test results for an area by samples that are extremely high or low in some soil property. It also allows for more sitespecific application of fertilizers, organic wastes, lime, etc. at appropriate rates, thus avoiding under- or over-application of these soil amendments. Nonrandom sampling requires a large number of soil samples and is usually done by establishing a field sample grid with a spacing of 15-30 m between grid intersection points. A composite soil sample is collected at each grid point by combining 8-10 soil cores collected from a 1 m diameter circle placed around the sample point. Grid spacing is a function of the intended land use and the anticipated degree of macro-variation. Note that a 15 and 30 m grid spacing will result in about 45 and 12 composite soil samples per ha, respectively, considerably more than the one sample per 8 ha associated with random sampling. Grid sampling has become more common in recent years with the advent of GIS and GPS technology and its use in precision agriculture (see Section 13.4). For areas with significant and identifiable meso-variation, as might occur when fertilizers are consistently placed in bands across a field, a more intensive random sampling pattern can be used to ensure that the average value is not skewed by either the very high value present in the fertilizer band or the lower value for the bulk soil located between the bands. The number of soil cores to be collected in these situations will usually be four or five times as great as those needed for a random, composite sample (i.e., as many as

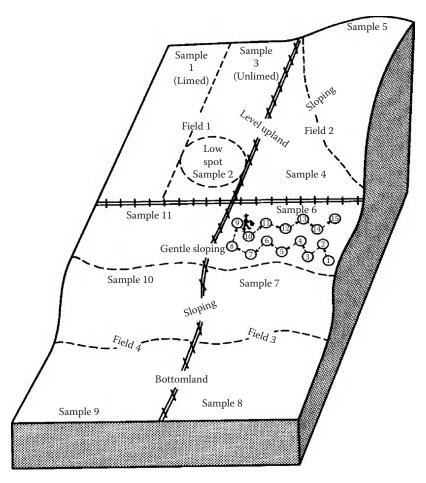

FIGURE 13.2 Illustration of soil sampling practices for uniform fields [Courtesy of Nebraska Agricultural Extension Service].

1–2 soil samples per ha). Finally, it should be noted that random and nonrandom sampling techniques are not appropriate for all aspects of soil fertility evaluation, particularly true for elements that are more mobile in the soil profile (e.g., NO_3 -N and SO_4 -S).

13.2.3.1.2 Soil Sampling Methods

The most important factors to consider in the soil sampling process are the depth of sampling, the time of year to sample, and the frequency of sampling. The depth to sample depends on the objectives of the soil fertility evaluation, including the crop to be grown, the nutrient of interest, the type of soil test to be performed, and the basis for resulting fertilizer recommendations. Soil samples for routine soil tests of plant nutrient availability and lime requirement are usually obtained from topsoils (0-20 cm depth). There are, however, a number of important exceptions to this general rule such as when soil tests are conducted for mobile soil nutrients (NO₃-N and SO₄-S), or to estimate the effect of pH on herbicide activity in no-till cropping systems, or for soil fertility evaluation for shallow or deeprooted crops, or to monitor the leaching of potential pollutants downward in the soil profile. Shallow soil sampling is most often recommended for conservation tillage systems where nutrients and lime are not incorporated with the soil by plowing, for permanent pastures and/or turf where root systems rarely extend below a depth of 10 cm, and to estimate the potential for P loss in erosion or runoff in watersheds where eutrophication is an important environmental concern (sample to 0-5 cm). Finally, it is important to review the source of soil test interpretations or fertility recommendations before deciding on a soil sampling depth. In the United States, recommendations often originate from a local or regional Land Grant University and different universities may have calibrated the same tests to different sampling depths. The recommended depth for subsoil sampling varies with the intent of the test. For example, subsoil testing for NO₃-N in arid regions may require that samples be taken to as deep as 1 m (60 cm is often recommended). Testing sandy soils in humid regions for SO₄-S may require a subsoil sample from the B horizon (usually 20-60 cm) where SO₄-S can accumulate by sorption to clays and Fe/Al oxides. Care should be taken to minimize contamination of the subsoil sample by topsoil when collecting subsoil samples, which can seriously influence results and subsequent recommendations.

The proper time of year to collect a soil sample and the frequency of soil sampling should also be considered. Soil samples can be collected at any time of the year when the ground is not frozen, although the ideal time is shortly before making a land management decision because this gives the most current indication of soil properties (fertility, pH). In general, for most

agricultural systems routine soil tests for lime and fertilizer recommendations are normally collected 3–6 months prior to planting a crop. This usually provides sufficient time for management decisions to be made and implemented in a timely manner. For example, if a soil test should recommend that limestone is needed to correct a problem with soil acidity, it is important to know this several months in advance of planting because of the time required for the limestone to react in the soil and raise the soil pH to the desired value. Soil testing well in advance of planting also allows time to change the plants to be grown if soil test results indicate that growing conditions are inappropriate for the plant specified. An exception is the pre-sidedress nitrate test for corn (PSNT) (see Section 13.2.4.4), which must be collected when corn plants are about 30 cm in height.

The frequency of soil testing varies somewhat with intended land use, such as the plants to be grown and the nutrient management practices required. Ideally, soils should be sampled at the same time of year (e.g., spring or fall) and at no more than 2–3 year intervals. Sampling at the same time of year minimizes the effect of seasonal variations on soil pH, which decreases during the summer as soluble salts increase in the soil from fertilization and mineralization of organic matter. Some studies have shown similar decreases in P and K during the year, with lower values reported in the fall than spring.

13.2.3.1.3 Soil Sample Handling

Proper handling of soil samples is necessary to prevent contamination and to minimize extreme changes in elemental concentrations or pH between the soil in the field and the sample that is analyzed in the laboratory. Handling includes the actual process of collecting soil cores, the mixing needed to prepare a composite sample, transporting the sample from the field to the laboratory, and the drying, grinding, sieving, and storing that occurs in the laboratory. A variety of tools are available to collect soil cores, including handheld soil probes and augurs, hydraulic soil coring devices, shovels, and hand trowels. The major consideration is to use sampling and mixing tools made of materials that will not contaminate the soil (e.g., stainless steel or plastic). Once collected, individual soil cores from the area of interest are composited by combining them in a clean container, preferably made of plastic to avoid contamination from painted or galvanized metal surfaces, mixing well, and removing a subsample that represents the entire mixture. During the sampling process avoid contamination from dirty or rusty sampling and mixing devices, fertilizer materials, galvanized metals (source of Zn), and paper bags that may contain boron (B). Soil samples should be delivered to the testing laboratory as soon as possible after collection to minimize any changes in elemental concentration that may take place prior to drying. The greatest concern is with NO₃-N, which can increase when soils are kept for extended periods in a warm, moist state (from mineralization of organic N and nitrification of exchangeable NH₄-N), or decrease when soils are maintained in a warm, wet state (from denitrification of NO₃-N). Once received by the laboratory, soil samples are normally dried at low temperatures (ambient to 50°C; avoid higher

temperatures), ground and sieved, typically to pass a 2 mm screen. The samples are then ready for analysis.

13.2.3.2 Soil Analyses: Overview of Chemical, Physical, and Biological Methods

Chemical analysis of soils is based on the principle that chemical solutions can rapidly, reproducibly, and inexpensively assess soil nutrient supplying capacity and other soil properties that affect plant growth (pH, soluble salts, organic matter). The most common chemical methods used are extraction and equilibration; others include titration (for acidity) and chemical or thermal oxidation (for organic matter).

Chemical extraction is almost always conducted with dried, ground, and sieved soil samples. For most soil tests the process involves scooping or weighing a small representative portion of the soil sample (from 1 to 10 cm³ or g) into an extracting vessel (flask, beaker, extraction bottle), adding a known volume of chemical extracting solution (from 10 to 100 mL), shaking rapidly for a short time period (from 5 to 30 min), filtering the sample, and analyzing the filtrate for the elements of interest. For example, extraction by the Mehlich 3 soil test, one of the most widely used extracting solutions in the United States involves scooping 2.5 cm³ of air-dried, sieved (2 mm) soil into a 100 mL plastic extraction bottle, followed by the addition of 25 mL of the Mehlich 3 solution (0.2 M CH₃COOH + 0.25 M NH₄NO₃ + $0.015\,\mathrm{M\ NH_4F} + 0.013\,\mathrm{M\ HNO_3} + 0.001\,\mathrm{M\ EDTA}$). The soil suspension is shaken for 5 min on a reciprocating shaker, filtered into 25 mL plastic vials, and analyzed by either atomic absorption spectrophotometry (AAS), inductively coupled plasma atomic emission spectroscopy (ICP-AES), or colorimetry to determine the concentration of each element in the soil extract. The principles of these instrumental methods are described in the Soil Science Society of America (SSSA) monograph Methods of Soil Analysis: Chemical Properties, Part 2 (Sparks, 1996).

Soil chemical properties are not always assessed by extraction methods. Another common chemical testing method is equilibration, in which a solution is added to the soil, the resulting suspension is shaken (or sits) for a short time period, and some property of the soil suspension is measured. This approach is used to measure soil pH and lime requirement, by use of an electrode that determines the chemical activity of hydrogen ions in a soil-water suspension (pH) or in a suspension of soil and a chemical buffer solution (lime requirement). A similar approach is used to measure soil soluble salts where a conductivity cell or bridge measures the specific conductance of a soil-water suspension. Some soil testing laboratories use titrimetric techniques to measure soil acidity by first extracting soil with a neutral salt solution (e.g., 1 M KCl), followed by titration of the acidic extractant with a dilute base (e.g., 0.1 M NaOH). Soil organic matter tests originally used wet chemical oxidation to estimate organic matter from the amount of carbon in soils that could be oxidized by K₂Cr₂O₇. Environmental concerns about the use and disposal of chromium (Cr) have caused most laboratories to now use high temperature oxidation (360°C) to estimate organic matter from weight loss upon ignition of a soil sample.

Most soil testing methods have been standardized by regional and national soil testing organizations and the SSSA. Consequently, numerous publications provide detailed, recommended methods (e.g., soil drying, grinding, sieving; preparation of extracting solutions; proper soil:solution extraction ratio, shaking rate, time and filtration method; and appropriate instrumental method). These publications are both national (Sparks, 1996; Jones, 1999; USDA-NRECS, 2004; Carter and Gregorich, 2007) and regional (SRIEG-18, 1992; NEC-67, 1995; NCR-13, 1998) in scope. Closely following these recommended methods is essential to accurately assess soil fertility.

13.2.3.3 Interpretation of Soil Testing Results

Interpretation of soil testing results may be defined as quantitatively relating the results of a soil analysis to the probability that a soil management activity will have the desired result. For soil fertility evaluation this means using soil test results to accurately predict crop yield without nutrient addition and the probability of a profitable plant response when fertilizers or other soil amendments (e.g., lime, manures, composts) are added. Interpreting soil test results for land uses where the desired result is not economically optimum plant yield (e.g., aesthetic value of ornamental plants in a horticultural setting; biodegradation of an organic pollutant in a bioremediation system; inactivation of a heavy metal in a polluted soil) requires that we are able to identify measures of success that can be quantitatively related to a soil test value and to soil management practices.

Soil test interpretation for agricultural systems begins with research that proves a statistical correlation exists between a soil test value and some aspect of plant response (e.g., nutrient concentration in the plant, crop yield). If the soil test and plant response are correlated the next step in interpretation is soil test calibration. The main goal of soil test calibration is to rate soils in terms of the probability that nutrient additions will be profitable (e.g., to divide the population of soil test values into responsive and nonresponsive categories; Table 13.1 and Section 13.2.6).

13.2.3.4 Recommendations Based on Soil Testing

Soil test recommendations must integrate soil test data with many other factors such as climate, economics, soil and crop management practices, management ability of the soil test user, and any considerations imposed by environmental protection. Soil test values tell us nothing about these other factors, instead we must rely on other sources of information, basic scientific principles, practical experience, and professional judgment to integrate them, with soil test results, into a reasonable recommendation.

The recommendation process starts with knowledge of the intended land use and factors that affect recommendations vary in importance with land use. Production agriculture recommendations usually include the rate, timing, and method of application of fertilizers, liming materials, and other soil amendments such as biosolids and manures. In this situation, where the goals are economically optimum crop yields and minimal environmental impact, recommendations are based on (1) current soil

TABLE 13.1 Generalized Soil Test Categories and Recommendations Based on Crop Response and Environmental Impact

Category Name	Category Definition	Recommendations
Crop response		
Below optimum (very low, low, medium)	The nutrient is considered deficient and will probably limit crop yield. There is a high to moderate probability of an economic yield response to adding the nutrient	Nutrient recommendations are based on crop response and will build soil fertility into the optimum range over time. Starter fertilizer may be recommended for some crops
Optimum (sufficient, adequate)	The nutrient is considered adequate and will probably not limit crop growth. There is a low probability of an economic yield response to adding the nutrient	If soils are tested annually, no nutrient additions are needed for the current crop. For other than annual soil testing, nutrient applications are often recommended to maintain the soil in the optimum range. Starter fertilizer may be recommended for some crops
Above optimum (high, very high, excessive)	The nutrient is considered more than adequate and will not limit crop yield. There is a very low probability of an economic yield response to adding the nutrient. At very high levels, there is the possibility of a negative impact on the crop if nutrients are added	No nutrient additions are recommended. At very high or excessive levels, remedial action may be needed to prevent phytotoxicity or environmental problems
Environmental response		
Potential negative environmental impact (very high, excessive)	Soils testing at this level or above have higher potential to cause environmental degradation and should be monitored closely. The likelihood of environmental problems depends on other site-specific characteristics (e.g., slope, hydrology, rainfall). This soil test level is independent of the crop response categories above and may be above or below the optimum level based on crop response	If other site factors minimize environmental impact, some nutrient additions may be recommended according to crop response guidelines. If other site factors indicate a potential environmental impact is likely, nutrient additions including starter fertilizer are not recommended. Remedial actions may be required to protect the environment

Source: Adapted from Beegle, D. 1995. Interpretation of soil test results, p. 84–91. In J.T. Sims, and A.M. Wolf (eds.) Recommended soil testing procedures for the Northeastern United States. Bull. no. 493. University of Delaware, Newark, DE.

test values and any other soil characteristics that affect a recommendation, such as soil drainage class; (2) the crop to be grown and the realistic yield potential for that crop; (3) soil test calibration data that indicate the degree of response expected to any soil amendment; (4) the source of nutrients and/or lime to be used and any restrictions on application method and timing that exist; (5) soil management history, such as the use of animal manures, biosolids, or growth of a leguminous cover crop; and (6) environmental parameters that may require modification of standard recommendations, such as soil leaching potential and depth to ground water and/or soil erosion and runoff potential and proximity to surface waters sensitive to eutrophication.

Not surprisingly, given the rather subjective nature of many components of the soil test recommendation process, several different recommendation philosophies have evolved for agricultural systems. These philosophies, contrasted in detail in Section 13.2.6, vary mainly in the approach used to maintain soil fertility in the range needed for optimum crop production. Some recommend more liberal and more frequent applications of nutrients to ensure that nutrient deficiency does not limit crop production. Others are more conservative, relying heavily on soil tests as the basis for any nutrient addition, often recommending that no nutrients be added when soils are in the optimum or excessive range. The decision on which philosophy to follow is primarily based on the current economics of production. However, for nutrients known to have environmental impacts (N, P), environmental-based recommendations to protect ground and surface water quality, even if the result is suboptimum crop performance, are now mandated or at least being considered in many regions.

13.2.4 Soil Testing Methods for Plant Nutrients

The intent of this chapter is to briefly describe, for each plant nutrient, (1) the major soil processes affecting the nutrient that are relevant to soil testing, (2) current soil test methods and recent advances in research, and (3) any factors that should be taken into consideration when conducting soil tests or interpreting soil test results. Other chapters in the *Handbook of Soil Science* provide reviews of nutrient cycling and should be consulted as necessary.

13.2.4.1 Phosphorus

13.2.4.1.1 Soil Phosphorus

Phosphorus in soils occurs in inorganic and organic forms that primarily originated from the weathering of calcium phosphate minerals, the most common being apatite (($Ca_{10}(X)_2(PO_4)_6$, where X is either F, Cl, OH, or CO₃). Approximately 30%–50% of the total P in most soils is found in the organic fraction. Chemical weathering of soil minerals and mineralization of organic matter release P into the soil solution where it exists in very low concentrations (0.003–0.3 mg P L⁻¹, average of ~0.05 mg P L⁻¹) almost exclusively as phosphate ions. In acid soils, dihydrogen phosphate ($H_2PO_4^-$) is the prevalent ion while hydrogen

phosphate (HPO₄²⁻) is the main phosphate species found above pH 7.2. Once in solution, phosphate can be assimilated by biological organisms; sorbed (chemically bound) to soil colloids such as clays, oxides of Fe and Al, and CaCO3; precipitate as an insoluble compound by reaction with Al and Fe in acid soils or Ca in calcareous soils; or be lost in surface or subsurface runoff. Phosphorus can be released back into the soil solution by mineralization of organic compounds, desorption of P from soil colloids, or the dissolution of solid phases of P. Plant available forms of soil P are mainly those found in the soil solution, sorbed by soil colloids, or precipitated as relatively soluble minerals. Mineralization of organic P and dissolution of very stable P minerals proceeds too slowly in most soils to provide a large percentage of the available P required for plant growth. Desorption (and dissolution) of P occurs when plant uptake decreases the P concentration in the soil solution, thermodynamically favoring the release of sorbed or solid phase P. Soil tests for P were designed to simulate this process, extracting P from sorbed forms and metastable precipitates by four processes: (1) acid dissolution, (2) anion exchange, (3) cation complexation, and (4) cation hydrolysis (Kamprath and Watson, 1980). For example the Bray P₁ soil test, developed for slightly acid and neutral soils where Al-P and Ca-P are major sources of plant available P, is a mixture of $0.025\,\mathrm{M}$ HCl + $0.03\,\mathrm{M}$ NH₄F. The F⁻ ion forms a strong complex with Al⁺³ in solution, causing dissolution of Al-P compounds, and the dilute HCl dissolves a proportion of the Ca-P and lesser amounts of Al-P and Fe-P. Together, NH4F and the HCl cause labile pools of soil P to release P into solution, similar to what would occur in soils in response to the depletion of soil solution P by plant uptake. In near neutral soils, the F- also reacts with Ca to form CaF2, enhancing dissolution of Ca-P. The Olsen soil test (0.5 M NaHCO₃, pH 8.5) functions similarly in calcareous soils where HCO₃- precipitates soluble Ca as CaCO₃ causing release of P from CaHPO₄. Soil P tests may also extract organic P either by direct acid hydrolysis of organic P esters or by enhancing P release from organo-metallic complexes (Al-OM, Fe-OM). Note that soil tests based on soluble P alone are not an accurate index of a soil's P supplying capacity because they do not reflect the capacity of the solid phase to replenish the solution phase as P uptake occurs. Nor would soil tests using very strong chemical reagents that cause extensive dissolution of mineral phases or oxidation of organic matter because they would overestimate plant available P.

Current soil testing methods for P: the soil testing methods commonly used for P today are shown in Table 13.2 and were reviewed extensively by Fixen and Grove (1990). The Bray P_1 , Ca-lactate, Morgan, and Olsen soil tests are only used to extract P while Mehlich 1, Mehlich 3, and AB-DTPA (NH₄HCO₃ + DTPA) are multielement soil tests used to extract P, K, Ca, Mg, and some micronutrients (Cu, Fe, Mn, Zn). As a general rule, the acidic extractants (Bray, Mehlich 1, Mehlich 3, Morgan) are used on acid soils and the alkaline extractants (AB-DTPA, Olsen) on calcareous soils. A number of studies, however, have shown that the Olsen P test may be an accurate test for a broader range of soils.

TABLE 13.2 Summary of Soil Testing Methods Currently Used for Phosphorus (P)

Soil Test	Extractant Composition	Comments, Critical Values, ^a and Sources
AB-DTPA	$\rm M~NH_4HCO_3 + 0.005Af~DTPA-pH~7.5$	Multinutrient extractant primarily used with alkaline soils. Critical value: ≥8 mg kg ⁻¹ (Soltanpour and Schwab, 1977)
Bray P_1	$0.03\mathrm{M~NH_4F} + 0.025\mathrm{M~HCl}$	Used only to extract P on acid soils with moderate CEC. Critical value: \geq 30 mg kg ⁻¹ (Bray and Kurtz, 1945)
Mehlich I	$0.05\mathrm{M}\mathrm{HCl} + 0.0125\mathrm{M}\mathrm{H}_2\mathrm{SO}_4$	Multinutrient extractant used on acidic, low CEC soils. Critical value: ≥25 mg kg ⁻¹ (Mehlich, 1953)
Mehlich III	$0.2\mathrm{M~CH_{3}COOH} + 0.25\mathrm{M~NH_{4}NO_{3}} + 0.015\mathrm{M}$ $\mathrm{NH_{4}F} + 0.013\mathrm{M~HNO_{3}} + 0.001\mathrm{M~EDTA-pH}~2.5$	Multinutrient extractant suitable for wide range of soils. Well correlated with Bray P₁, Mehlich I, and Olsen P. Critical value: ≥50 mg kg⁻¹ (Mehlich, 1984)
Morgan and modified Morgan	Morgan: 0.7 M NaC ₂ H ₃ O ₂ + 0.54 M CH ₃ COOH + —pH 4.8 modified Morgan: 0.62 M NH ₄ OH + 1.25 M CH ₃ COOH—pH 4.8	Multinutrient extractant primarily used in the northeast United States for acid, low CEC soils. Not suitable for calcareous soils. Critical value: ≥4-6 mg kg ⁻¹ (Morgan, 1941)
Olsen	0.5 M NaHCO₃—pH 8.5	Originally developed as P extractant for alkaline soils in the western United States; now also used for acid and neutral soils. Critical value: ≥10 mg kg ⁻¹ (Olsen et al., 1954)
Egner	$ \begin{array}{l} \textrm{P-CAL: 0.01 M Ca lactate + 0.02 M HCl P-AL:} \\ 0.10 \textrm{M NH}_4 \textrm{lactate + HOAc-pH 3.75} \end{array} $	Multinutrient extractant used in Europe and Scandinavia but not in the United States. (Egner et al., 1960)

^a Critical value is defined as the soil test concentration above which the soil test level is considered optimum for plant growth and responses to additions of the nutrient are unlikely to occur. Critical values cited in this table are approximate, can be affected by soil type and crop, and were obtained from several sources.

Two soil testing approaches for P, the P_i soil test and ion exchange resins, do not remove P from soils by chemical extraction. The P_i test was developed and evaluated in the late 1990s and early 2000s and showed considerable promise, but still has not been adopted as a routine soil test (Myers et al., 1995, 1997, 2005; Chardon et al., 1996; Menon et al., 1997). In this method, the soil is equilibrated with 0.01 M CaCl, in the presence of an Fe-oxide-coated filter paper strip, which acts as an "infinite sink" for soil P. Phosphorus in solution is sorbed to the strip, causing desorption of labile P from the soil. After a specified equilibration period (usually 2h) the strip is removed, rinsed lightly to remove soil particles, and sorbed P is extracted from the strip by shaking for 2h with a 1 M H₂SO₄ solution. Ion exchange resins have been used for many years in soil P research to study the desorption of soil P (Amer et al., 1955; Sibbesen, 1978; Wolf et al., 1985; van Raij et al., 1986; Sharpley et al., 1989; Abrams and Jarrell, 1992; Mallarino and Atia, 2005; Saavedra et al., 2007). These studies have shown that anion exchange resins saturated with Cl or HCO3 and suspended with soils in aqueous suspensions can accurately estimate labile P in soils of widely differing properties. Resins simulate root uptake by removing P from solution by surface sorption processes, with the rate of P sorption controlled by diffusion (Kuo, 1996). Despite this research, ion exchange resins have not been adopted as routine soil tests for P in the United States primarily because of practical difficulties such as separating the resin from the soil after the equilibration process. To overcome these obstacles Skogley et al. (1990) developed an encapsulated ion exchange resin technique for use by routine soil testing laboratories as a multinutrient soil test (commonly referred to as the phytoavailability soil test, or PST; see also Skogley, 1994). Similar efforts have occurred in other countries such as Brazil, where van Raij (1994) successfully adapted ion exchange resin beads for use as multinutrient

soil tests by routine soil testing laboratories. Ion exchange resins and chemical extractions can also be used as environmental soil P tests, to identify soils with a higher potential for P loss in soil erosion and surface or subsurface runoff (see Section 13.2.7).

13.2.4.1.2 Considerations in Soil Testing for P

The soil testing process for P is rather straightforward. Soil samples for P can be collected at any time during the year because P is relatively immobile in most soils. The standard sample depth is $0-20\,\mathrm{cm}$, except for permanent pastures and turf $(0-10\,\mathrm{cm})$. In fields where the use of banded fertilizers containing P is a common practice it may be necessary to significantly increase the number of soil samples collected per unit area to overcome the high meso-variation that can be present (see Section 13.2.3.1). For situations where the transport of P to surface waters by erosion and runoff is a concern samples should be collected from the 0-5 cm depth, since runoff waters only interact with the upper few centimeters of the soil surface (Sharpley and Smith, 1989; Sharpley et al., 1996). There are no special handling or storage requirements for samples collected for P analysis—air drying, grinding, and sieving with a 2 mm screen is the standard approach. Analysis of P in soil extracts can be done colorimetrically by the molybdenum blue method, which primarily measures orthophosphate (Murphy and Riley, 1962) or by ICP-AES, which measures orthophosphate and some organic P. Note that ICP-AES values for soil test P can often be 5%–10% higher than those measured colorimetrically.

Interpretation of analytical results for P must consider the fact that P moves to roots primarily by diffusion, a process that is highly dependent upon soil moisture and temperature. It is not uncommon to see early season P deficiency in crops grown in soils that are rated as "optimum" or "excessive" in P. Low soil temperatures and dry soil conditions can inhibit diffusion, root growth,

and plant uptake of P, creating a temporary P deficiency that often disappears as soils warm and receive rainfall or irrigation. In most cases, if soils have optimum concentrations of plant available P, early season deficiencies have no significant negative effects on crop yield. For the most part, however, soil P tests are interpreted using the sufficiency level approach described in Table 13.1.

13.2.4.2 Soil Testing for Potassium, Calcium, and Magnesium

13.2.4.2.1 Soil K, Ca, and Mg

The cycling and plant availability of K, Ca, and Mg are sufficiently similar that these three nutrients can be considered together for the purposes of soil fertility evaluation. The primary sources of plant available K, Ca, and Mg are soil minerals, which release these ions into solution during the weathering process.

Major K-bearing minerals include the feldspars (orthoclase, microcline, sanidine) and micas (biotite, muscovite, phlogopite). Total K concentrations in soils average 1.9%, but can range from 0.03% in organic soils (peats, mucks), to 0.3% in very sandy soils, to as high as 3.0% in mineral soils derived from feldspars and micas. Once mineral dissolution has occurred, soil K is primarily found in soluble, exchangeable, and nonexchangeable forms. Potassium in the soil solution ranges in concentration from 1 to $80 \,\mathrm{mg} \,\mathrm{K} \,\mathrm{L}^{-1}$ (average = $2-5 \,\mathrm{mg} \,\mathrm{K} \,\mathrm{L}^{-1}$) and is in rapid equilibrium with exchangeable K that is retained by electrostatic attraction to the negatively charged cation exchange sites located on clays and soil organic matter. Usually, less than 5% of the total CEC of a soil is occupied by exchangeable K. Soluble and exchangeable K are the major sources of plant-available K in most soils but together represent less than 1%-2% of total soil K. Nonexchangeable K, also referred to as "fixed" K, is found within the interlayers and on the edges of 2:1 expanding clay minerals and is viewed as a slowly available reserve of K for plant uptake. Soluble K is <1% of exchangeable soil K and can be quickly depleted by plant uptake or leaching. The ability of soils to maintain an adequate concentration of K in solution by releasing K from exchangeable and nonexchangeable forms is referred to as the K buffer capacity and is an important measure of soil fertility. The K buffer capacity of soils depends largely upon the amount and types of clay minerals present and to a lesser extent on soil organic matter content. Soils with higher percentages of clay, especially 2:1 clays, have higher K buffer capacities than sandy or organic soils and more ability to maintain soluble K in an optimum range for plant growth.

Major mineral sources of soil Ca are carbonates, feldspars, and phosphates. The most important Ca-bearing mineral is anorthite (CaAl $_2$ Si $_2$ O $_3$; a plagioclase feldspar), except in calcareous soils of arid regions where calcite (CaCO $_3$) and dolomite (CaMg(CO $_3$) $_2$) dominate. Total soil Ca varies widely, from <0.1% in highly weathered, tropical soils to as high as 25% in calcareous soils. Typical total soil Ca values in noncalcareous, humid, temperate soils are from 0.7% to 1.5%; total Ca values >3% indicate the presence of CaCO $_3$. In most soils, Ca is the dominant exchangeable cation, occupying 20%–80% of the total CEC. Consequently, soil solution concentrations of Ca are quite high relative to most other plant nutrients, ranging from 30 to 300 mg Ca L $^{-1}$ in noncalcareous soils.

Plant available Mg originates from the weathering of minerals such as biotite, dolomite, hornblende, olivine, and serpentine. Total soil Mg varies from <0.1% in coarse, sandy soils of humid regions to 4% in fine-textured soils formed from Mg-bearing minerals. As with K and Ca, soluble and exchangeable Mg are most important to plant growth. Exchangeable Mg occupies from 4% to 20% of total soil CEC and soluble Mg ranges from 50 to 120 mg Mg $\rm L^{-1}$ in temperate region soils.

13.2.4.2.2 Current Soil Testing Methods for K, Ca, and Mg

Soil chemical extraction is by far the most common approach used today to test soils for plant-available K, Ca, and Mg and most extracting solutions simultaneously extract and analyze soluble and exchangeable K, Ca, and Mg (Table 13.3). Haby et al.

TABLE 13.3 Summary of Soil Testing Methods Currently Used for Potassium (K), Calcium (Ca), and Magnesium (Mg)

Soil Test Extractant	Extractant Composition	Comments, Critical Values, ^a and Sources
Ammonium acetate	M NH $_4$ OAc, pH 7.0	Used for >50 year as soil test for K, Ca, and Mg (Chapman and Kelley, 1930; Schollenberger and Simon, 1945). Suited for wide range of soils, but primarily used in midwestern and western states of the United States. Critical values for K, Ca, and Mg vary widely based on soil type (pH, CEC, clay mineralogy) and crop and reportedly range from K: 110–200 mg kg ⁻¹ ; Ca: 250–500 mg kg ⁻¹ ; and Mg: 30–60 mg kg ⁻¹ (Haby et al. 1990)
AB-DTPA	$M NH_4HCO_3 + 0.005 M DTPA—pH 7.5$	Multinutrient extractant primarily used with alkaline soils (Soltanpour and Schwab, 1977)
Mehlich I	$0.05\mathrm{M}\;\mathrm{HCl} + 0.0125\mathrm{M}\;\mathrm{H_2SO_4}$	Multinutrient extractant used on acidic, low CEC soils (Mehlich, 1953)
Mehlich III	$0.2 \mathrm{M} \mathrm{CH_3COOH} + 0.25 \mathrm{M} \mathrm{NH_4NO_3} + \\ 0.015 \mathrm{M} \mathrm{NH_4F} + 0.013 \mathrm{M} \mathrm{HNO_3} + \\ 0.001 \mathrm{M} \mathrm{EDTA} - \mathrm{pH} 2.5$	Multinutrient extractant suitable for wide range of soils (Mehlich, 1984)
Morgan and modified Morgan	Morgan: $0.7 \mathrm{M} \mathrm{NaC_2H_3O_2} + 0.54 \mathrm{M}$ CH ₃ COOH +—pH 4.8	Multinutrient extractant primarily used in the northeast United States for acid, low CEC soils. Not suitable for calcareous soils (Morgan, 1941)
	Modified Morgan: 0.62 M NH ₄ OH + 1.25 M CH ₃ COOH—pH 4.8	

^a Critical value is defined as the soil test concentration above which the soil test level is considered optimum for plant growth and responses to additions of the nutrient are unlikely to occur. Critical values cited in this table are approximate, can be affected by soil type and crop, and were obtained from several sources.

(1990) surveyed soil testing laboratories in the United States and Canada and reported that the most common soil test for K, Ca, and Mg was ammonium acetate (1 M NH₄OAc, pH 7.0), which has been used in the United States since the 1930s. Since then, multielement soil testing extractants, such as AB-DTPA and Mehlich 3 have gained wide popularity and are fast becoming the standard soil test method for K, Ca, and Mg. The more widespread use of multielement extractants can be attributed to the fact that many soil testing laboratories formerly used one extracting solution for P (e.g., Bray P1), another for K, Ca, and Mg (e.g., 1M NH₄OAc, pH 7.0), and another for micronutrients (e.g., DTPA). Converting to multielement extractants thus reduced the cost and time of analysis. Most soil test extractants for K, Ca, and Mg displace these cations from exchange sites on soil colloids with a replacing cation, usually NH₄+ (NH₄OAc, AB-DTPA), Na+ (Morgan), H+ (Mehlich 1) or a combination of cations (Mehlich 3, Modified Morgan). All extractants also remove any solution K, Ca, and Mg present in the soil. Acidic soil tests (e.g., Mehlich 1, Mehlich 3) may also extract some nonexchangeable K from soils containing 2:1 clays because the H+ ion is small enough to enter the interlayers of these minerals and displace K from interlayer exchange sites. Acidic extractants may also overestimate exchangeable Ca and Mg in arid region calcareous soils because they may dissolve Ca- and Mg-bearing minerals. One recent advance in soil K testing has been the use of sodium tetraphenylboron (NaTB) to extract plant available K. Cox et al. (1999) showed in greenhouse studies that a 5 min NaTB soil extraction was well correlated with plant K uptake and suggested that NaTB effectiveness was due to its ability to extract both exchangeable and nonexchangeable K. Fernández et al. (2008) in a field study with soybeans found NaTB to work reasonably well but that is was not as effective overall as 1 M NH₄OAc at predicting plant K uptake.

A few alternatives to chemical extraction have been used for routine evaluation of plant available K, Ca, and Mg. Two that have received the most interest have been ion exchange resins, used in a few U.S. states and some South American countries (van Raij et al., 1986; Skogley, 1994), and electro-ultrafiltration (EUF), which has primarily been used in Europe (Nemeth, 1979; Haby et al., 1990). The basic principles of ion exchange resin techniques were discussed earlier in Section 13.2.4.1. The EUF method combines electrodialysis and ultrafiltration and has been used as a multielement extractant for NH₄+, NO₃-, P, K, Ca, Mg, Na, S, B, Mn, and Zn. In this approach, a soil suspension is stirred in a central compartment attached to cells on each side containing platinum electrodes. Microfiber filters separate the soil suspension from the electrodes. Voltage is applied to the electrodes and vacuum filtration is used to withdraw water and dissolved ions from the central cell after specified time intervals that characterize different forms of plant nutrients (e.g., the 0-5 min extraction is soluble K, the 5-10 min extraction is exchangeable K, and the 10-30 min extraction reflects K buffering capacity). Solutions collected at the anode and cathode sides of the EUF device are combined and analyzed by standard instrumental techniques. While EUF

has been shown to be an effective method to simultaneously extract plant-available nutrients, it is rather slow and expensive and not as widely used as chemical soil tests (Haby et al., 1990; van Lierop and Tran, 1985).

13.2.4.2.3 Considerations in Soil Testing for K, Ca, and Mg

Soil samples for K, Ca, and Mg analysis are collected following the standard approaches described in Section 13.2.3.1. The most important exception is with K where subsoil samples are sometimes recommended for soils with a very sandy surface horizon and a shallow B horizon (zone of clay accumulation). In these situations subsoil K has been shown to be an important source of plant available K and testing the surface horizons alone may underestimate the true K supplying capacity of the soil. This is particularly true if the B horizon has a high percentage of 2:1 clays that can act as a reservoir of slowly available, nonexchangeable K. Subsoil samples are rarely tested for Ca and Mg. Samples should be collected at the same time each year to minimize the effect of natural, seasonal changes in K concentrations caused by processes such as leaching, freezing, and thawing, biological transformations (uptake, mineralization, biocycling of K from subsoils to topsoils), and seasonal differences in soil moisture content.

Soil sample handling, particularly drying method, can markedly and unpredictably alter extractable K. Air-drying will usually cause an increase in exchangeable K except in soils that have very high K values, where drying results in K fixation into nonexchangeable forms, thus decreasing soil test K. Changes caused by drying are greatest in fine-textured soils dominated by 2:1 clays. While it can be argued that soil tests for K would best be conducted on field-moist soils, virtually all laboratories air-dry soils to ease handling, grinding, sieving, mixing, and weighing of a representative subsample. These advantages outweigh the changes in extractable K that occur during drying; however, soils to be analyzed for K should only be air-dried at moderate temperatures (<50°C) because oven-drying, particularly at >60°C greatly enhances the release of K from soils. Analyses of soil extracts for K, Ca, and Mg can be conducted by either AAS or ICP-AES.

Interpretation of soil test results for K, Ca, and Mg follows the sufficiency level approach (Table 13.1) with only a few minor modifications related to soil type, plant to be grown, and soil/crop management. Soil test K interpretations are often modified based on the CEC of the soil. Soils with higher CEC values will often have a higher "critical value" (point above which crop response is not expected and thus no fertilizer is recommended). As an example, the critical value for soil test K in Alabama (Mehlich 1 soil test) increases from 40 to 80 mg K kg⁻¹ as CEC increases from 4.5 to 9.0 cmol kg⁻¹. Subsoil K is occasionally considered when interpreting the results of a soil test for K, usually by the use of indirect information on subsoil properties, such as soil survey data on horizonation (e.g., depth to B horizon), texture, and clay mineralogy. Other factors that may alter a soil test-based recommendation for K fertilization include crop and yield goal that affect K removal, tillage practices, and climate, which affects release of K from K-bearing minerals.

Modification of the results of a soil test for Ca or Mg by inclusion of other information is unusual. In general, maintaining soils in an adequate pH range for plant growth by use of the proper type of liming material is adequate to maintain Ca and Mg fertility in most soils.

13.2.4.3 Sulfur

13.2.4.3.1 Soil S

The total S content of temperate zone soils ranges from 0.005% to 0.04%, more than 90% of which is found in organic forms. Total S values can be much higher in arid and semiarid regions where soils can accumulate soluble and mineral forms of sulfate-S (SO₄-S), such as gypsum (CaSO₄·2H₂O), epsomite (MgSO₄·7H₂O), and mirabilite (Na₂SO₄·10H₂O). Important S-bearing minerals in humid regions are pyrite (Fe₂S), sphalerite (ZnS), and chalcopyrite (CuFeS₂). Sulfur originating from burning fossil fuels, particularly coal, or S emissions from volcanic activity, wetlands, and oceans can also be added to the soils by wet or dry atmospheric deposition.

The plant available form of S is the sulfate anion (SO₄²⁻-S), which originates from the dissolution of soluble salts and minerals containing S, oxidation of elemental S, and mineralization of organic S. Solution SO₄-S can be taken up by plants, immobilized in microbial biomass, sorbed by soil colloids, precipitated in an insoluble mineral form by reaction with Ca, Mg, or Na, or leached to subsoils. If plant roots penetrate to subsoils, sorbed SO₄-S can be released into solution and absorbed. Under reducing conditions, SO₄-S can be converted to H₂S gas and lost from the soil by volatilization or precipitated as metal sulfide minerals such as pyrite. Traditionally, S deficiency has been considered uncommon except with high yielding crops grown on deep sandy soils with low organic matter contents or on soils that developed from parent materials low in S. Organic matter mineralization and wet deposition of SO₄-S resulting from the burning of fossil fuels typically have provided enough plant available S for most crops. Concentrations of SO₄-S in the soil solution (A horizon) of most temperate zone soils ranged from 5 to 20 mg SO₄-S L⁻¹, higher than the 3-5 mg SO₄-S L⁻¹ required for the optimum growth of most plants. However, recently, S deficiencies have been reported globally due to a combination of factors, the primary factor being a marked decrease in S deposition due to air pollution control measures. Sulfate deposition has clearly decreased over the past 20 years as indicated by the National Atmospheric Deposition Program (NADP, 2008). For example, the average total wet deposition of sulfate at the Huntington Wildlife Station in Essex County, New York, United States, was 22 kg-SO₄ ha⁻¹ for the period of 1979–1983 and decreased 43% to $14 \text{kg-SO}_4 \text{ ha}^{-1}$ for the period of 2003–2007 (NADP, 2009). This decrease in atmospheric deposition combined with increased crop yields and decreased agronomic S inputs are expected to contribute to increasing S deficiencies in crops (McGrath and Zhao, 1995). These predictions have been supported by recent studies showing increased yield responses to S fertilization in previously nonresponsive soils (Chen et al., 2008).

13.2.4.3.2 Current Soil Testing Methods for S

Due to the historic lack of crop response to S fertilization, less effort has been directed toward the development and calibration of soil tests for S than for P and K. Soils tested for S are normally sampled from the A horizon, except in sandy, low organic matter soils with shallow B horizons that can be a significant reserve of plant available SO_4 -S. In these situations soil testing laboratories may request a subsoil sample because the subsoil may have enough available S for plant growth.

Soil testing for S relies on chemical extraction. More than 20 extracting solutions have been developed and evaluated as S soil tests, including water and various concentrations of dilute acids (HCl), dilute salts (e.g., CaCl2, LiCl, NaCl, NH4Cl), acetates (e.g., NH₄OAc, MgOAc, NaOAc), and phosphates (e.g., Ca(H₂PO₄)₂, KH₂PO₄) (Johnson and Fixen, 1990). Most extractants remove soluble and sorbed forms of SO₄-S, along with a small percentage of organic S, as these are the soil fractions regarded as plant available. In arid regions where the concentration of SO₄-S is often quite high due to the accumulation of sulfate salts, extraction with deionized or distilled water is used to identify S deficiency. In humid regions, the use of an extractant that contains a replacing anion such as phosphate is often more successful. One of the most widely used extracting solutions for S is a 500 mg P L-1 solution of Ca(H₂PO₄)₂, sometimes in combination with 2 M HOAc. The phosphate ions displace sorbed SO₄-S, the Ca ions cause flocculation of the soil allowing for ease of analysis of S by either colorimetric or turbidimetric means, and the HOAc extracts some organic S. Recently there has been interest in using Mehlich 3 as a S soil test to eliminate the need for a separate extraction to determine available S. Once extracted, SO₄-S can be analyzed by colorimetry, titrimetry, ion chromatography, and ICP-AES. The most common analytical techniques are turbidimetry (if S is determined alone) and ICP-AES (for S alone and in multielement analyses). A review of the advantages and disadvantages of analytical methods for S is given by Tabatabai (1996).

13.2.4.3.3 Interpretation of S Soil Tests

Sulfur soil testing is a moderately reliable approach to determine the S fertility status of a soil but is best used in conjunction with other information, such as plant analysis, knowledge of soil type and plant yield potential, soil organic matter content, and inputs of S from sources other than fertilizers (e.g., manures, crop residues, rainfall, and irrigation waters). A major concern with soil testing for S is that inputs of S from the atmosphere or irrigation waters, which can be more than the rates of S fertilizer recommended, are not accounted for by soil testing. In situations where S deficiency is probable, based on knowledge of the soils, crops, and management practices it may be more economical to apply a small amount of S fertilizer (10–15 kg S ha⁻¹) than to incur the costs of soil testing for S.

13.2.4.4 Soil Testing for Nitrogen

Nitrogen deficiency is the most common soil fertility problem for nonlegumes. Nitrogen (N) is also well known to negatively impact water and air quality. However, despite the importance of N to agricultural production and environmental quality we have not yet developed a widely accepted method to routinely and rapidly test soils for plant available N, particularly in humid regions. The reasons for this center around the complex transformations undergone by N in soils, referred to as the soil N cycle. A summary of the key aspects of the N cycle most relevant to soil testing follows; C.4 and D.1 in the *Handbook of Soil Sciences*, and elsewhere (Keeney, 1982; Keeney and Nelson, 1982; Power and Schepers, 1989; Tisdale et al., 1993; Pierzynski et al., 1994; Foth and Ellis, 1997; Schepers and Raun, 2008) provide thorough treatments of N cycling, management, and environmental impacts.

Most of the N available for biological assimilation by plants and animals originated from the atmosphere, which is 78% N₂ by volume. Only a small fraction of the global N supply is in soils where total N values typically range from 0.05% to 0.15% and most of the N (>98%) is organic in nature. Atmospheric N is converted to forms of N that can be directly or indirectly used by plants by symbiotic or nonsymbiotic biological N fixation. Bacteria of the genera Rhizobium and Bradyrhizobium can form symbiotic relationships with plants to assimilate N₂ from the atmosphere while nonsymbiotic N fixation can be conducted by free-living algae, bacteria, and actinomycetes. Electrical discharges and industrial processes that combine N2 with H from natural gas to produce the ammonia (NH3) used in fertilizer manufacture also convert atmospheric N to fixed forms that can be used by plants. The burning of fossil fuels and volcanic eruptions are also atmospheric sources of N to soils.

The key components of the soil N cycle are as follows: (1) mineralization, in which soil organic N is converted to inorganic NH₄-N by microbial decomposition; (2) immobilization, in which soil microorganisms assimilate NH₄-N and NO₃-N from the soil solution for population growth and biomass production—essentially the reverse of mineralization; (3) nitrification, in which certain soil bacteria convert NH₄-N to NO₃-N, a rapid process in most well-aerated soils; (4) ion exchange in which NH₄-N is retained by cation exchange sites on soil clays or organic matter (including fixation within the interlayers of 2:1 clays as nonexchangeable NH₄-N) and NO₃-N is retained by any positively charged sites present on soil colloids (rarely of consequence in most soils); (5) denitrification, in which soil bacteria that are more active under reduced conditions convert NO₃-N to gaseous forms of N (N₂O, NO, N₂), which are then lost from soils to the atmosphere; (6) volatilization, in which NH₄-N is converted to gaseous NH₃-N under certain alkaline conditions (high pH) and lost to the atmosphere; and (7) leaching, in which NO₃-N moves downward in the soil profile with percolating waters.

Plants absorb N from the soil solution as NH_4 -N and NO_3 -N. An accurate soil test for N, therefore, must be able to predict how all components of the soil N cycle that affect the availability of

NH₄-N and NO₃-N can be integrated into a quantitative assessment of a soil's N supplying capacity. This is a complex task given the dependence of N cycling on biological activity and environmental conditions (temperature, moisture, rainfall). The fact that the main form of inorganic N in most soils is NO₃-N further complicates the matter given the leachability of NO₃-N and its sensitivity to loss as a gas via denitrification.

13.2.4.4.1 Current Soil Testing Methods for N

Soil testing for N differs markedly between arid and humid regions. In arid (or semiarid) regions evapotranspiration usually exceeds precipitation and inorganic forms of soil N are not as susceptible to leaching or denitrification. For this reason a soil sample collected from a crop's rooting zone shortly before the start of the growing season and analyzed for residual inorganic N (the NH₄-N and NO₃-N remaining from the past year's mineralization, fertilization, and organic waste applications) accurately measures plant available soil N. Nitrogen inputs are then reduced in proportion to the amount of residual inorganic N. In most cases soil samples for residual inorganic N must be collected to deeper depths (as much as 180 cm, minimum of 60 cm) than for standard soil testing (20 cm). Soil samples tested for residual inorganic N are often only analyzed for NO₃-N since this is usually the dominant form of inorganic N in most soils. The best time to take a soil sample for residual inorganic N is usually just before planting or early in the growing season, although in very cold and dry areas, where mineralization and leaching are minimal, samples can be collected the preceding fall or winter.

After sample collection, proper handling is critical to avoid changes during storage that affect the amount of inorganic N present. Moist soils stored under warm conditions can mineralize or immobilize a significant amount of inorganic N; very wet samples can lose NO₃-N by denitrification. To avoid problems soil samples should be rapidly air-dried at ambient temperatures by spreading the soil in a thin layer. Extraction of inorganic N is usually accomplished by shaking a dried, ground soil sample for 30 min to 1 h with a salt solution (e.g., 2 M KCl, 0.01 M CaSO₄, $0.04 \,\mathrm{M} \,(\mathrm{NH_4})_2(\mathrm{SO_4})$, followed by filtration. The most common methods to determine NH₄-N and NO₃-N in soil extracts are automated colorimetry and ion chromatography. Other, less commonly used methods are steam distillation, ion specific electrodes, and microdiffusion techniques. Details on the various methods used to measure inorganic N in soils are given by Bundy and Meisinger (1996) and an extensive review of chemical extraction methods to assess soil N availability was recently prepared by Griffin (2008).

Soil testing for N in humid regions is a more complex process and a less accurate predictor of soil N fertility, and consequently most soil testing laboratories in humid regions do not offer routine soil N tests. The greater rainfall and warmer temperatures in humid areas can cause rapid seasonal changes in the amount of inorganic N present in the soil profile making direct measures of residual inorganic N estimates of plant available N less reliable.

The general consensus on soil testing for residual inorganic N in humid regions is that this practice has value if conducted at or near planting and if samples are collected to a reasonable depth in the soil profile (not just the topsoil). If residual inorganic N values are high, reductions in N inputs should be made. Bundy et al. (1992) reported on the use of the preplant soil profile nitrate test (PPNT) in the upper Midwestern United States where moderate rainfall and cooler winter temperatures make this approach more likely to be successful than in warmer, higher rainfall humid regions. The economically optimum N fertilizer rate for corn (Zea mays, L.) was shown to decrease in a near-linear manner with increasing PPNT values in soil samples collected to a depth of 1 m. Another situation where residual inorganic N testing has been successful in humid regions has been with short-season crops where there is less likelihood that significant losses of residual inorganic N will occur.
